CHAPTER 65

Epilepsy

SUSAN J. ROGERS AND JOSE E. CAVAZOS

KEY CONCEPTS

1. Patient-specific treatment goals should be identified as early as possible.
2. Accurate diagnosis and classification of seizure/syndrome type is critical to selection of appropriate pharmacotherapy.
3. Patient characteristics such as age, comorbid conditions, ability to comply with the prescribed regimen, and presence or absence of insurance coverage can also influence the choice of antiepileptic drugs.
4. Pharmacotherapy of epilepsy is highly individualized and requires titration of the dose to optimize antiepileptic drug therapy (maximal seizure control with minimal or no side effects). Approximately 50% to 70% of patients can be maintained on one antiepileptic drug.
5. If the therapeutic goal is not achieved with monotherapy, a second drug can be added or a switch to an alternative single antiepileptic drug can be made. If a second antiepileptic drug is added it should have a different mechanism of action from the first, although there is no clear evidence in humans to support this.
6. Some patients eventually can discontinue antiepileptic drug therapy. Several factors predict successful withdrawal of antiepileptic drugs.
7. The appropriate use of antiepileptic drugs requires a thorough understanding of their clinical pharmacology, including mechanism of action, pharmacokinetics, adverse reactions, and drug interactions, as well as available dosage forms.

Epilepsy is a disorder that is best viewed as a symptom of disturbed electrical activity in the brain, which may have many etiologies. It is a collection of many different types of seizures that vary widely in severity, appearance, cause, consequence, and management. Seizures that are prolonged or repetitive can be life-threatening. Epilepsy is defined by the occurrence of at least two unprovoked seizures separated by 24 hours.[1] The effect epilepsy has on patients' lives can be significant and extremely frustrating. It is also important to recognize that seizures can be just one (albeit the most obvious) symptom of an epileptic disorder. Not uncommonly, patients have other comorbid disorders, including depression, anxiety, and potentially neuroendocrine disturbances. Patients with epilepsy also may display neurodevelopmental delay, memory problems, and/or cognitive impairment. Although, by convention, the focus of drug treatment is on the abolition of seizures, clinicians must also try to address these common comorbidities.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

Each year, 120 per 100,000 people in the United States come to medical attention because of a newly recognized seizure.[1] At least 8% of the general population will have at least one seizure in a lifetime. However, it is common to have a seizure and not have epilepsy. The rate of recurrence of a first unprovoked seizure within 5 years ranges between 23% and 80%. Children with an idiopathic first seizure and a normal electroencephalogram (EEG) have a particularly favorable prognosis. Some seizures occur as single events resulting from withdrawal of central nervous system (CNS) depressants (e.g., alcohol, barbiturates, and other drugs) or during acute neurologic illnesses or systemic toxic conditions (e.g., uremia or eclampsia). Some patients will have seizures only associated with fever. These febrile seizures do not constitute epilepsy.[1]

The age-adjusted incidence of epilepsy is 44 per 100,000 person-years. Each year, approximately 125,000 new epilepsy cases occur in the United States; only 30% are in people younger than 18 years of age at the time of diagnosis. There is a bimodal distribution in the occurrence of the first seizure, with one peak occurring in newborn and young children and the second peak occurring in patients older than 65 years of age. The relatively high frequency of epilepsy in the elderly is now being recognized.

ETIOLOGY

Seizures occur because a group of cortical neurons discharge abnormally in synchrony. Anything that disrupts the normal homeostasis or stability of neurons can trigger hyperexcitability and seizures. Thousands of medical conditions can cause epilepsy, from genetic mutations to traumatic brain injury. A genetic predisposition to seizures has been observed in many forms of primary generalized epilepsy. Patients with mental retardation, cerebral palsy, head injury, or strokes are at an increased risk for seizures and epilepsy. The more profound the degree of mental retardation as measured by the intelligence quotient (IQ), the greater is the incidence of epilepsy. In the elderly, the onset of seizures is typically associated with focal neuronal injury induced by strokes, neurodegenerative disorders (e.g., Alzheimer's disease), and other conditions. In some cases, if an etiology of seizures can be identified and corrected, the

patient may not require chronic antiepileptic drug (AED) treatment. Patients can also present with unprovoked seizures that do not have an identifiable cause, and thus by definition have idiopathic or cryptogenic epilepsy. *Idiopathic etiology* is the term used for suspected genetic cause, whereas *cryptogenic etiology* is used if no obvious cause is found for focal-onset seizures.

Many factors have been shown to precipitate seizures in susceptible individuals. Hyperventilation can precipitate absence seizures. Excessive sleep, sleep deprivation, sensory stimuli, emotional stress, and hormonal changes occurring around the time of menses, puberty, or pregnancy have been associated with the onset of or an increased frequency of seizures. A careful drug history should be obtained from patients presenting with seizures because theophylline, alcohol, high-dose phenothiazines, antidepressants (especially maprotiline or bupropion), and street drug use have been associated with provoking seizures. Perinatal injuries and small gestational weight at birth are also risk factors for the development of partial-onset seizures. Immunizations have not been associated with an increased risk of epilepsy.

PATHOPHYSIOLOGY

Seizures result from excessive excitation, or in the case of absence seizures, from disordered inhibition of a large population of cortical neurons.[2] This is reflected on EEG as a sharp wave or *spike*. Initially, a small number of neurons fire abnormally. Normal membrane conductances and inhibitory synaptic currents break down, and excess excitability spreads, either locally to produce a focal seizure or more widely to produce a generalized seizure. This onset propagates by physiologic pathways to involve adjacent or remote areas. The clinical manifestations depend on the site of the focus, the degree of irritability of the surrounding area of the brain, and the intensity of the impulse.[2]

There are multiple mechanisms that might contribute to synchronous hyperexcitability, including: (1) alterations in the distribution, number, type, and biophysical properties of ion channels in the neuronal membranes; (2) biochemical modifications of receptors; (3) modulation of second messaging systems and gene expression; (4) changes in extracellular ion concentrations; (5) alterations in neurotransmitter uptake and metabolism in glial cells; and (6) modifications in the ratio and function of inhibitory circuits. In addition, local neurotransmitter imbalances could be a potential mechanism for focal epileptogenesis. Transitory imbalances between the main neurotransmitters, glutamate (excitatory) and γ-aminobutyric-acid (GABA) (inhibitory), and neuromodulators (e.g., acetylcholine, norepinephrine, and serotonin) might play a role in precipitating seizures in susceptible patients.[2]

Control of abnormal neuronal activity with AEDs is accomplished by elevating the threshold of neurons to electrical or chemical stimuli or by limiting the propagation of the seizure discharge from its origin. Raising the threshold most likely involves stabilization of neuronal membranes, whereas limiting the propagation involves depression of synaptic transmission and reduction of nerve conduction.[2]

Prolonged seizures and continued exposure to glutamate can result in neuronal injury in vulnerable neuronal populations resulting in functional deficits, primarily in memory, and in permanent changes of wiring of the neuronal circuitry. Sprouting and reorganization of neuronal projections might lead to a chronic susceptibility to seizures, neuronal destruction, and brain damage. However, limited degree of neurogeneisis in the hippocampal pathways has been induced by epileptic seizures. The role of these newly born neurons is not well understood.

CLINICAL PRESENTATION

The International League Against Epilepsy has proposed two major schemes for the classification of seizures and epilepsies: the International Classification of Epileptic Seizures and the International Classification of the Epilepsies and Epilepsy Syndromes.[3,4] The International Classification of Epileptic Seizures (Table 65–1) combines the clinical description with certain electrophysiologic findings to classify epileptic seizures. Seizures are divided into two main pathophysiologic groups—partial seizures and generalized seizures—by EEG recordings and clinical symptomatology.

Partial (focal) seizures begin in one hemisphere of the brain and—unless they become secondarily generalized—result in an asymmetric motor manifestation. Partial seizures manifest as alterations in motor functions, sensory or somatosensory symptoms, or automatisms. Partial seizures with no loss of consciousness are classified as *simple partial* (SP). In some cases, patients will describe somatosensory symptoms as a "warning" prior to the development of a generalized tonic clonic (GTC) seizure. These warnings are, in fact, simple partial seizures and frequently are termed auras.

Partial seizures with an alteration of consciousness are described as *complex partial* (CP). With CP seizures, the patient can have automatisms, periods of memory loss, or aberrations of behavior. Some patients with CP epilepsy have been mistakenly diagnosed as having psychotic episodes. CP seizures also can progress to GTC seizures. Patients with CP seizures typically are amnestic to these events. A partial seizure that becomes generalized is referred to as a *secondarily generalized seizure*.

Generalized seizures have clinical manifestations that indicate involvement of both hemispheres. Motor manifestations are bilateral, and there is a loss of consciousness. Generalized seizures can be further subdivided by EEG and clinical manifestations. Generalized absence seizures are manifested by a sudden onset, interruption of ongoing activities, a blank stare, and possibly a brief upward rotation of the eyes. They generally occur in young children through adolescence. It is important to differentiate absence seizures from complex partial seizures.

TABLE 65-1 International Classification of Epileptic Seizures

I. Partial seizures (seizures begin locally)
  A. Simple (without impairment of consciousness)
    1. With motor symptoms
    2. With special sensory or somatosensory symptoms
    3. With psychic symptoms
  B. Complex (with impairment of consciousness)
    1. Simple partial onset followed by impairment of consciousness–with or without automatisms
    2. Impaired consciousness at onset–with or without automatisms
  C. Secondarily generalized (partial onset evolving to generalized tonic-clonic seizures)
II. Generalized seizures (bilaterally symmetrical and without local onset)
  A. Absence
  B. Myoclonic
  C. Clonic
  D. Tonic
  E. Tonic-clonic
  F. Atonic
  G. Infantile spasms
III. Unclassified seizures
IV. Status epilepticus

Data from Commission on the Classification and Terminology of the International League Against Epilepsy.[3,4]

With GTC seizures there is a sudden sharp tonic contraction of muscles followed by a period of rigidity and clonic movements. During the seizure, the patient may cry or moan, lose sphincter control, bite the tongue, or develop cyanosis. After the seizure, the patient may have altered consciousness, drowsiness, or confusion for a variable period of time (postictal period) and frequently goes into a deep sleep. Tonic and clonic seizures can also occur separately.

Brief shock-like muscular contractions of the face, trunk, and extremities are known as *myoclonic jerks*. They can be isolated events or rapidly repetitive. A sudden loss of muscle tone is known as an *atonic seizure*, which may present as a head drop, the dropping of a limb, or a slumping to the ground. These patients often wear protective head ware to prevent trauma.

The International Classification of Epilepsies and Epilepsy Syndromes adds components such as age of onset, intellectual development, findings on neurologic examination, and results of neuroimaging studies to define epilepsy syndromes more fully. Syndromes can include one or many different seizure types (e.g., Lennox-Gastaut syndrome). The syndromic approach includes seizure type(s) and possible etiologic classifications (e.g., idiopathic, symptomatic, or unknown). *Idiopathic* describes syndromes that are presumably genetic but also those in which no underlying etiology is documented or suspected. A family history of seizures is commonly present, and neurologic function is essentially normal except for the occurrence of seizures. *Symptomatic* cases involve evidence of brain damage or a known underlying cause. A *cryptogenic* syndrome is assumed to be symptomatic of an underlying condition that cannot be documented. Unknown or undetermined is used when no cause can be identified. This syndromic classification requires more information and is more important for prognostic determinations and response to treatment than for a classification based simply on seizure type.

CLINICAL PRESENTATION OF EPILEPSY

General

In most cases, the healthcare provider will not be in a position to witness a seizure. Many patients (particularly those with CP or GTC seizures) are amnestic to the actual seizure event. Obtaining an adequate history and description of the ictal event (including time course) from a witness is critically important. With treatment the typical clinical presentation of the seizure may change.

Symptoms

Symptoms of a specific seizure will depend on seizure type. Although seizures can vary between patients, they tend to be stereotyped within an individual.

- CP seizures can include somatosensory or focal motor features.
- CP seizures are associated with altered consciousness.
- Absence seizures can be almost nondetectable with only very brief (seconds) periods of altered consciousness.
- GTC seizures are major convulsive episodes and are always associated with a loss of consciousness.

Signs

Interictally (between seizure episodes), there are typically no objective or pathognomonic signs.

Laboratory Tests

There are currently no diagnostic laboratory tests for epilepsy. In some cases, particularly following GTC (or perhaps CP) seizures, serum prolactin levels can be transiently elevated. Laboratory tests can be done to rule out treatable causes of seizures (e.g., hypoglycemia, altered electrolyte concentrations, infections, etc.) that do not represent epilepsy.

Other Diagnostic Tests

- EEG is very useful in the diagnosis of various seizure disorders.
- An epileptiform EEG is found in only approximately 50% of the patients who have epilepsy.
- A prolactin serum level obtained within 10 to 20 minutes of a tonic-clonic seizure can be useful in differentiating seizure activity from pseudoseizure activity but not from syncope.[5]
- Although magnetic resonance imaging (MRI) is very useful (especially imaging of the temporal lobes), a computed tomography (CT) scan typically is not helpful except in the initial evaluation for a brain tumor or cerebral bleeding.

TREATMENT

DESIRED OUTCOME

1 The ideal goal of treatment for epilepsy is complete elimination of seizures and no side effects with an optimal quality of life (QOL). The best QOL is associated with a seizure-free state.[6] Often, however, a balance between efficacy and side effects must be accepted. With the older AEDs used as monotherapy, fewer than 50% of patients become seizure free.

Because therapy is continued for many years (often a lifetime), chronic side effects must be considered. If the patient is overly sedated or develops other significant side effects, some seizure control may have to be sacrificed to improve functioning. The patient should be involved in deciding what balance between frequency of seizures and the occurrence of side effects is most appropriate. The newer AEDs offer alternatives for balancing seizure frequency and drug side effects.

Providing optimal QOL also requires assessing all the concerns of patients with epilepsy, such as, issues about driving, economic security, forming relationships, safety, social isolation, social stigma, and so on. Patients with epilepsy can also have other neuropsychiatric comorbidities such as depression, anxiety, and sleep disturbances that need treatment.[7,8] Depression has been shown to have a significant impact on QOL in the patient with treatment-resistant epilepsy.[9]

GENERAL APPROACH TO TREATMENT

2 The general approach to treatment involves assessment of seizure type and frequency, identification of treatment goals, development of a care plan, and a plan for follow-up evaluation. During the assessment phase, it is critical to establish an accurate diagnosis of the seizure type and classification in order to select the appropriate initial AEDs. Patient-specific treatment goals must be identified, and these can change over time. Despite appropriate AED treatment, approximately 30% to 35% of patients are refractory to treatment. In this setting, seizure freedom may not be obtained, and more obtainable goals should be established (e.g., decrease in the number of seizures and minimized drug adverse effects).

3 Patient characteristics such as age, medical condition, ability to comply with a prescribed regimen, and insurance coverage also should be explored because these can influence AED choices or help to explain nonadherence to the regimen, a lack of response, or unexpected adverse effects.

Once the assessment is complete, for patients with new-onset seizures, the choice is whether to use drug therapy and, if so, which one. For a patient with long-standing epilepsy, adequacy of the current medication regimen must be evaluated. An AED should not be considered ineffective unless the patient has experienced unacceptable adverse effects with continued seizures.

4 If a decision is made to start AED therapy, monotherapy is preferred, and approximately 50% to 70% of all patients with epilepsy can be maintained on one drug.[10,11] However, many of these patients are not seizure free. The percentage of patients who are seizure free on one drug varies by seizure type. After 12 months of treatment, the percentage who are seizure free is highest for those who have only GTC seizures (48%–55%), lowest for those who have only CP seizures (23%–26%), and intermediate for those with mixed seizure types (25%–32%).[11] Combining AEDs with different mechanisms of action to achieve freedom from seizures may be advantageous, although this approach is as yet unproven. Approximately 65% of patients can be expected to be maintained on one AED and be considered well controlled, although not necessarily seizure free.

5 Of the 35% of patients with unsatisfactory control, 10% will be well controlled with a two-drug treatment. Of the remaining 25%, 20% will continue to have unsatisfactory control despite multiple drug treatment. There may be a genetic predisposition to epilepsy that is refractory to drug therapy. Some of these patients may become candidates for surgery or vagal nerve stimulator.

Once the care plan is established, an AED is selected. Patient education and assurance of patient understanding of the plan are essential. Detailed directions regarding titration, what to do in the event of a treatment-emergent side effect, and what to do if a seizure occurs must be provided to patients. Documentation of the assessment, care plan, and educational process is essential. Providing the patient with a seizure and side-effect diary will assist in the follow-up and evaluation phase. At the follow-up stage of treatment (which can be done in the hospital, clinic, pharmacy, or by phone), the treatment goals must be reviewed. If the goal has been achieved, new goals should be identified. For example, if the GTC seizures are now controlled, the goal may be to control partial seizures. If a patient fails to respond to the first AEDs, trials with other AEDs should be attempted as appropriate. Completion of the evaluation often requires a reassessment of the patient and development of a new care plan taking into account patient compliance, efficacy, and safety of the initial treatment.

Medication noncompliance can be the single most common reason for treatment failure. It is estimated that up to 60% of patients with epilepsy are noncompliant.[12] The rate of noncompliance is increased by the complexity of the drug regimen and by doses taken 3 and 4 times a day. Frequent uncontrolled seizures can also predispose a patient to noncompliance secondary to confusion over whether the drug was taken. Noncompliance is not influenced by age, sex, psychomotor development, or seizure type.[12]

Difference of opinion exists on the most appropriate time to initiate AED therapy. Treatment decisions vary depending on individual patient clinical characteristics and circumstances. Some clinicians start AED treatment after the first seizure, whereas others do not initiate treatment until a second, unprovoked seizure has occurred. Still others initiate prophylactic treatment following a CNS insult thought likely to cause epilepsy eventually (e.g., stroke or head trauma). Drug treatment may not be indicated when seizures have minimal impact on patients' lives or when there has been only a single seizure. If a patient presents after a single isolated seizure, one of three treatment decisions can be made: treat, possibly treat, or do not treat. These decisions are based on the probability of the patient having a second seizure (Table 65–2). For patients with no risk factors, the probability of a second seizure is less than 10% in the first year and approximately 24% by the end of 2 years. If risk factors are present, the recurrence rate can be as high as 80% after 5 years.[13] The decision on whether to start AED therapy often depends on patient-specific factors such as epilepsy syndrome, seizure etiology, presence of a neuroanatomic defect, and the EEG, as well as, the patient's lifestyle and preferences. Patients who have had two or more seizures generally should be started on AEDs.

TABLE 65-2 Recurrence Risk for Patients Experiencing One Unprovoked Seizure

Type of Patient	First-Year Risk (%)	Fifth-Year Risk (%)
Adults with single unproved seizure		34
No CNS insult	10	29
Influence of family history		
Sibling with seizure	29	46
No sibling with seizures	7	27
EEG patterns		
GSW on EEG	15	58
Normal EEG	9	26
Occurrence of previous seizure	10	39
Caused by an illness or childhood febrile seizure		
Remote symptomatic with Todd paresis	26	48
	41	75
Status epilepticus at onset	37	56
Prior acute seizure	60	80
Idiopathic	10	29

CNS, central nervous system; EEG, electroencephalogram; GSW, generalized spikes and waves.
Data from Leppik[13] and Gross-Tsur et al.[15]

WHEN TO STOP ANTIEPILEPTIC DRUGS

6 The AEDs used to control seizures may not need to be given for a lifetime. Polypharmacy can be reduced, and some patients can discontinue AEDs altogether. The drug considered less appropriate for the seizure type (or the agent deemed most responsible for adverse effects) should be discontinued first. In some cases, decreasing the number of AEDs can decrease side effects and increase cognitive abilities. This improvement in cognition may be small, especially if the patient is on a drug that primarily affects psychomotor speed with less effect on higher-order cognitive functioning.

7 Factors favoring successful withdrawal of AEDs include a seizure-free period of 2 to 4 years, complete seizure control within 1 year of onset, an onset of seizures after age 2 but before age 35, and a normal neurologic examination and EEG. Factors associated with a poor prognosis in discontinuing AEDs, despite a seizure-free interval, include a history of a high frequency of seizures, repeated episodes of status epilepticus, a combination of seizure types, and development of abnormal mental functioning. A 2-year seizure-free period is suggested for absence and rolandic epilepsy, whereas a 4-year seizure-free period is suggested for SP, CP, and absence seizures associated with tonic-clonic seizures. AED withdrawal generally is not suggested for patients with juvenile myoclonic epilepsy, absence with clonic-tonic-clonic seizures, or clonic-tonic-clonic seizures. The American Academy of Neurology (AAN) has issued guidelines for discontinuing AEDs in seizure-free patients.[14] After assessing the risks and benefits to both the patient and society, AED withdrawal can be considered in a patient meeting the following profile: seizure free for 2 to 5 years, a history of a single type of partial seizure or primary GTC seizures, a normal neurologic exam and normal IQ, and an EEG that has normalized with treatment. When these factors are present, the relapse rate is expected to be less than 32% for children and 39% for adults.

AED withdrawal should be done gradually, especially in patients with profound developmental disabilities. Some patients will have a recurrence of seizures as the AEDs are withdrawn. Sudden withdrawal is associated with the precipitation of status epilepticus. Withdrawal seizures are of particular concern for agents such as benzodiazepines and barbiturates. Seizure relapse has been reported to be more common if these AEDs are withdrawn over 1 to 3 months compared to over 6 months.

The risk of seizure relapse has been estimated at 10% to 70%. A meta-analysis determined that the relapse rate was 25% after 1 year and 29% after 2 years. Recurrence of seizures tends to occur early with at least one-half of the recurrences within 6 months of AED withdrawal and 60% to 90% within 1 year. Patients who relapse will generally become seizure free and in remission after AEDs are restarted although not necessarily immediately. The underlying epilepsy syndrome appears to determine prognosis for long-term remission.[15]

CLINICAL CONTROVERSY

It is not entirely clear which patients with epilepsy will require lifelong treatment. Although many clinicians feel that AED therapy is lifelong, others would argue that certain patients with idiopathic epilepsy and a normal neurologic examination and EEG are candidates for AED withdrawal following a prolonged period of seizure freedom (e.g., greater than 2–3 years). A large amount of the data supporting discontinuing AEDs has been obtained from children. Some adults will be reticent to discontinue AED therapy even if the clinician is in favor of it because of the fear of having a seizure and the consequences (e.g., loss of driver's license) that it would entail. The patient should agree and must be a willing participant in the plan to reduce or withdraw AED therapy.

NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy for epilepsy includes diet, surgery, and vagus nerve stimulation (VNS). A vagal nerve stimulator is an implanted medical device that is FDA approved for use as adjunctive therapy in reducing the frequency of seizures in adults and adolescents older than 12 years of age with partial-onset seizures that are refractory to AEDs. It is also used off-label in the treatment of refractory primary generalized epilepsy. The mechanisms of antiseizure actions of VNS are unknown. Human clinical studies have shown that VNS changes the cerebrospinal fluid (CSF) concentration of inhibitory and stimulatory neurotransmitters and activates specific areas of the brain that generate or regulate cortical seizure activity through increased blood flow. There is experimental evidence to suggest that the anticonvulsant effect of VNS is mediated by the locus coeruleus.[16]

The VNS device is relatively safe. It may also have a positive effect on mood and behavior, often independent of seizure reduction. The most common side effect associated with stimulation is hoarseness, voice alteration, increased cough, pharyngitis, dyspnea, dyspepsia, and nausea. Serious adverse effects reported include infection, nerve paralysis, hypoesthesia, facial paresis, left vocal cord paralysis, left facial paralysis, left recurrent laryngeal nerve injury, urinary retention, and low-grade fever. In the VNS studies, the percentage of patients who achieved a 50% or greater reduction in their seizure frequency (responders) ranged from 23% to 50%.

Surgery is the treatment of choice in selected patients with refractory focal epilepsy.[17] The success rate is beteen 80% and 90% in properly selected patients. Surgery reduces the risk of epilepsy-associated death, and it may also improve depression and anxiety in refractory epilepsy patients.[18,19] A recent systematic review/meta-analysis of published evidence of temporal lobe patients with pharmacoresistent epilepsy concluded that the combination of surgery with medical treatment is four-times as likely as medical treatment alone to achieve freedom from seizures.[20] A National Institutes of Health Consensus Conference identified three absolute requirements for surgery. They are (1) an absolute diagnosis of epilepsy, (2) failure on an adequate trial of drug therapy, and (3) definition of the electroclinical syndrome. A focus in the temporal lobe has the best chance for a positive outcome; however, extratemporal foci can be excised successfully in more than 75% of patients. The procedure is not without risk. Learning and memory can be impaired postoperatively, and general intellectual abilities are also affected in a small number of patients. Surgery may be particularly useful in children with intractable epilepsy. Patients may need to continue AED therapy for a period of time following successful epilepsy surgery, but dosage reduction may be achieveable.[17,21]

The ketogenic diet, devised in the 1920s, is high in fat and low in carbohydrates and protein, and it leads to acidosis and ketosis. Protein and calorie intake are set at levels that will meet requirements for growth. Most of the calories are provided in the form of heavy cream and butter. No sugar is allowed. Vitamins and minerals are supplemented. Medium-chain triglycerides can be substituted for the dietary fats. Fluids are also controlled. It requires strict control and parent compliance. Although some centers find the diet useful for refractory patients, others have found that it is poorly tolerated by patients. Long-term effects include kidney stones, increased bone fractures, and adverse effects on growth.[22] An international consensus statement has been published which offers recommendations for the clinical management of the patient with epilepsy using various forms of the ketogenic diet which may help with tolerability, including the use of the modified Atkins diet and the Low Glycemic Index Treatment.[23]

PHARMACOLOGIC THERAPY

Optimal management of epilepsy requires that AED treatment be individualized. Different patient groups (e.g., children, women of child-bearing potential, and the elderly) may be better suited to receive one AED than another by virtue not only of seizure type but also of susceptibility or relative risk for certain adverse effects. These issues are highlighted further below.

7 Selection and optimization of AED therapy require not only an understanding of drug mechanism(s) of action and spectrum of clinical activity but also an appreciation of pharmacokinetic variability and patterns of drug-related adverse effects. An AED must be effective for the specific seizure type being treated. The drug treatments of first choice depend on the type of epilepsy, and drug-specific adverse effects and patient preferences. Ultimately, AED effectiveness is the result of the interaction of each of these factors. A suggested algorithm for a general approach to the treatment of epilepsy is shown in Figure 65–1.

Table 65–3 provides evidenced-based treatment recommendations by three professional/regulatory bodies.[24–28] In addition, recommendations from a U.S. panel of experts, which included more recent drug treatment data compared to the AAN-American Epilepsy Society (AES) recommendations are included.[29]

The mechanism of action of most AEDs can be categorized as (1) affecting ion channel kinetics, (2) augmenting inhibitory neurotransmission, or (3) modulating excitatory neurotransmission. Augmentation in inhibitory neurotransmission includes increasing CNS concentrations of GABA, whereas efforts to decrease excitatory neurotransmission are primarily focused on decreasing

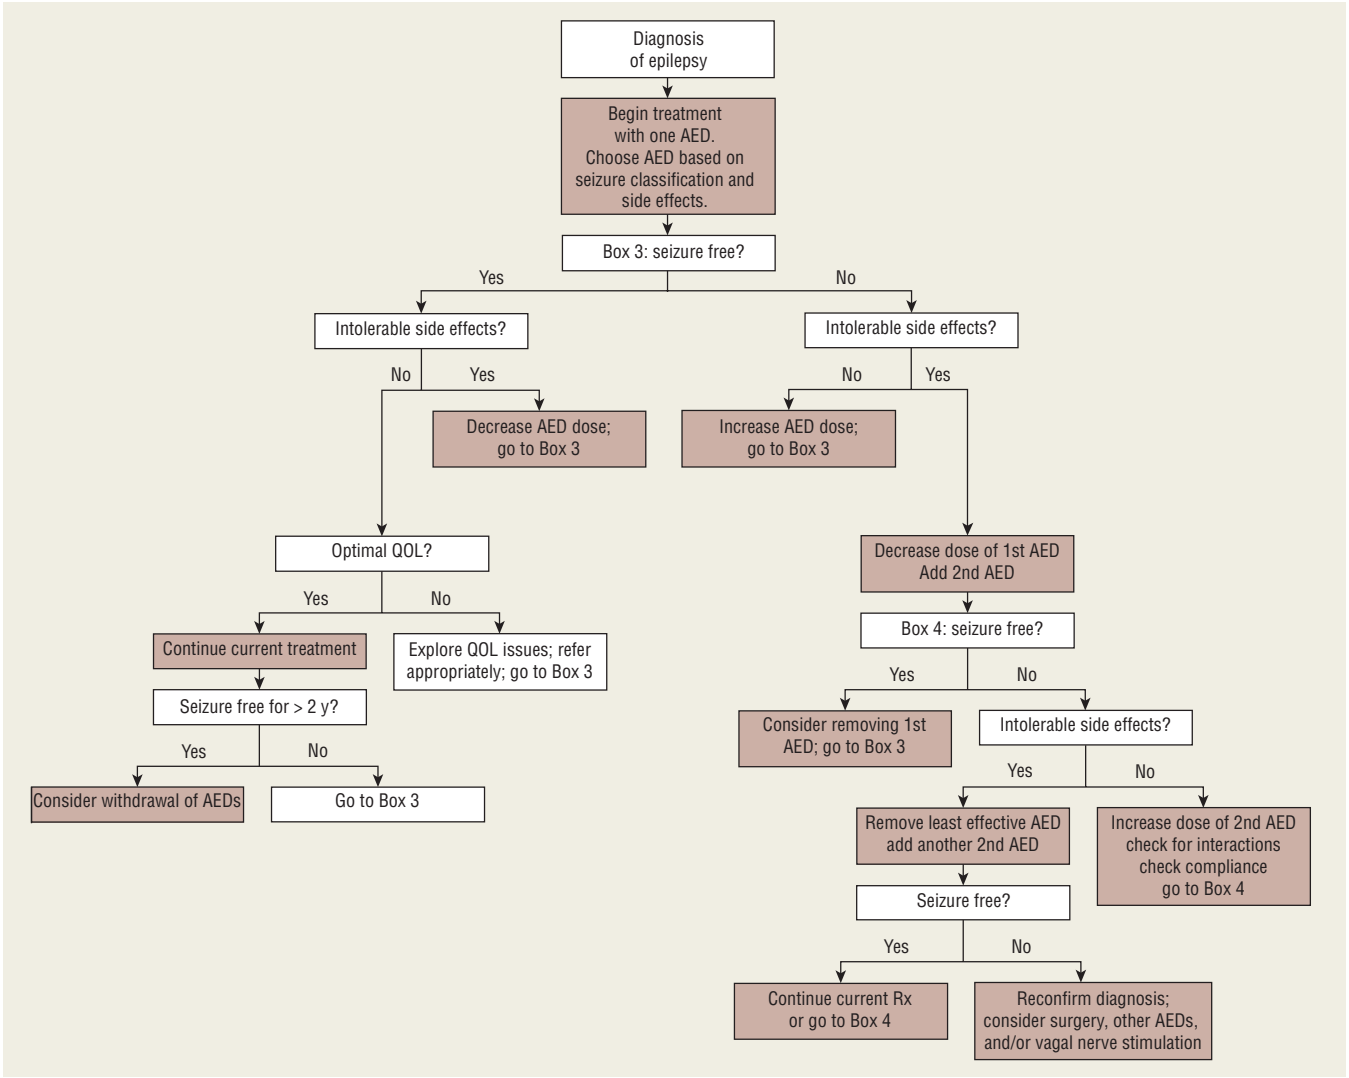

FIGURE 65-1. Algorithm for the treatment of epilepsy. (AED, antiepileptic drug; QOL, quality of life.)

(or antagonizing) glutamate and aspartate neurotransmission. AEDs that are effective against GTC and partial seizures probably reduce sustained repetitive firing of action potentials by delaying recovery of sodium channels from activation. Drugs that reduce corticothalamic T-type calcium currents are effective against generalized absence seizures. Myoclonic seizures respond to drugs that enhance $GABA_A$-receptor inhibition. In addition to mechanism of action, awareness of pharmacokinetic properties (Table 65–4), adverse effects (Table 65–5), AED-AED interactions (Table 65–6), and AED metabolic pathway as well as inducer or inhibitory effects on liver (Table 65–7) can aid in the optimization of AED therapy. Pharmacokinetic interactions are a common complicating factor in AED selection. Interactions can occur in any of the pharmacokinetic processes: absorption, distribution, metabolism or elimination. Caution should be used when AEDs are added to or withdrawn from a drug regimen.

Adverse effects of AEDs can be divided into acute and chronic (see Table 65–5). Acute effects can be dose/serum concentration—related or idiosyncratic. Concentration-dependent effects are common and troublesome but not usually life-threatening. Neurotoxic adverse effects are encountered commonly and can include sedation, dizziness, blurred or double vision, difficulty with concentration, and ataxia. In many cases these effects can be alleviated by decreasing the dose or avoided in some cases by titrating the dose upward very slowly. Most idiosyncratic reactions are mild, but they can be more serious if the hypersensitivity involves one or more organ systems. Other idiosyncratic side effects including hepatitis or blood dyscrasias are serious but rare.

Acute organ failure, when it occurs, generally occurs within the first 6 months of AED therapy. Unfortunately, laboratory screening evaluations of blood and urine typically are not helpful in predicting or detecting the early stage of severe reactions and generally are not recommended in asymptomatic patients. An exception to this is in the screening of patients of Southeast Asian heritage for HLA-B*1502 antigen who are to receive carbamazepine and possibly phenytoin. There is a strong association between the presence of this antigen and Stevens—Johnson syndrome.[36] In any patient, laboratory assessment, including white blood cell counts and liver function tests, may be reasonable if the patient reports an unexplained illness (e.g., lethargy, vomiting, fever, or rash).[37] It is important to note that patients dosed and maintained within "therapeutic ranges" are also capable of experiencing toxicities to AEDs.[32] Another potential long-term adverse effect of AED treatment is osteomalacia and osteoporosis.[38,39] The bone disorders associated with AED use are a heterogeneous group of disorders, ranging from asymptomatic high-turnover disease, with findings of normal bone mineral density, to markedly decreased bone mineral density sufficient to warrant the diagnosis of osteoporosis. While the etiology of

these osteopathies is uncertain, it has been hypothesized that certain drugs, including phenytoin, phenobarbital, carbamazepine, oxcarbazepine, felbamate, and valproic acid, may interfere with vitamin D metabolism. Whether the other AEDs cause these effects is unknown, however, current evidence suggests that lamotrigine does not. Common laboratory findings in these patients include elevated bone-specific alkaline phosphatase concentration, intact parathyroid hormone, and decreased serum calcium and 25-OH vitamin D concentrations. Patients receiving these drugs should receive supplemental vitamin D and calcium, as well as bone mineral density testing if other risk factors for osteoporosis are present.

The comparative effects of AEDs on cognition have been difficult to evaluate because of differences or inconsistencies in study design, seizure types studied, control for serum drug concentrations, and the neuropsychologic tests used. In general, there are not large differences between the older drugs, although the barbiturates phenobarbital and primidone appear to cause more cognitive impairment than other commonly used AEDs.[40,41] Phenytoin, particularly when serum concentrations are above the commonly accepted therapeutic range, may have a greater effect on motor function and speed. Among the older AEDs, valproic acid may cause less impairment of cognition. Improvement in cognition has been reported in patients switched from phenytoin or phenobarbital to valproic acid. However, these improvements are subtle if patients are in the same relative area of the therapeutic range. Patients changed from polytherapy to monotherapy also may demonstrate improvement in cognition. Some of the newer agents are believed to cause fewer neurobehavioral or cognitive effects. Among the newer AEDs, gabapentin and lamotrigine have been shown in several studies to cause fewer cognitive impairments compared with older agents, such as carbamazepine.[42–44] Conversely, topiramate may cause substantial cognitive impairment, particularly when used at high doses or during rapid dose escalation.[44] In addition, these patients may not be fully aware of their deficits.[45,46] AED treatment itself may sometimes worsen seizures due to improper AED selection for a specific seizure type or syndrome or can represent a paradoxical toxic effect of the drug.[47]

Because most adult patients have localization-related (partial-onset) seizures, the most widely used AEDs traditionally have been carbamazepine, phenobarbital, phenytoin, and valproic acid.

TABLE 65-7 Antiepileptic Drugs Elimination Pathways and Major Effects on Hepatic Enzymes

For CP seizures, these AEDs have similar efficacy.[48,49] Of these, carbamazepine and phenytoin are the most commonly prescribed AEDs for partial seizures in the United States. This preference is largely based on data derived from two landmark trials conducted through the Veterans Administration (VA) Epilepsy Cooperative Study Group. In the first of these trials, patients with new-onset partial or generalized epilepsy were randomized to receive either carbamazepine, phenobarbital, phenytoin, or primidone.[48] After 3 years, patients who received either carbamazepine or phenytoin were equally likely and patients on phenobarbital or primidone were least likely to have remained on their originally assigned treatment. Thus, carbamazepine and phenytoin were considered the drugs of first choice in patients with new-onset partial or generalized seizures. Carbamazepine was associated with fewer side effects. A follow-up study using almost identical methods compared carbamazepine and valproic acid.[49] Carbamazepine- and valproic acid—treated groups had equal retention rates for tonic-clonic seizures. Carbamazepine was superior to valproic acid for efficacy in the treatment of partial seizures. Valproic acid caused slightly more adverse effects.

Based primarily on these trials, carbamazepine has been recognized as the AED of first choice for partial seizures. Several of the newer generation AEDs are now proving to be reasonable alternatives. The newer AEDs were first approved as adjunctive therapy for patients with refractory partial seizures. Monotherapy trials with several of these newer agents including lamotrigine, gabapentin, topiramate, oxcarbazepine and levetiracetam have now been completed.[50–52] Comparisons between lamotrigine and older agents including carbamazepine and phenytoin as initial monotherapy for partial seizures have been conducted in Europe, and the results suggest comparable effectiveness and perhaps better tolerability for lamotrigine, particularly in elderly patients. In a large, unblinded, randomized, controlled trial in hospital based outpatient clinics in the United Kingdom, lamotrigine was found to be clinically better than carbamazepine for time to treatment failure outcomes in newly diagnosed patients with partial seizures; lamotrigine was determined to be a cost effective alternative to carbamazepine. Other drugs studied in this trial were gabapentin, oxcarbazepine, and topiramate.[53] Results from a VA cooperative trial designed to compare gabapentin, lamotrigine, and carbamazepine in newly diagnosed elderly patients with partial seizures found that lamotrigine efficacy is comparable with that of both gabapentin and carbamazepine, and is better tolerated than carbamazepine but equal to gabapentin in this population.[54] Clinical data suggest that in newly diagnosed patients, oxcarbazepine is as effective as phenytoin, valproic acid, and immediate-release carbamazepine, with perhaps fewer adverse effects. Close examination of the conversion to monotherapy trials suggests that oxcarbazepine demonstrates efficacy even in patients who previously had an inadequate response to carbamazepine, in spite of their structural similarity. Lastly, levetiracetam in a one-year study was found to have equal efficacy and tolerability when studied against controlled-release carbamazepine.[55]

In addition, several monotherapy trials using an active control or pseudoplacebo design also have been conducted. Although these study designs provide evidence of efficacy for the newer drugs, because the comparison is between active drug and placebo in patients who continue to have seizures in spite of current treatment with standard AEDs, it is difficult to compare the efficacy of the newer drugs directly with the older AEDs. Generally speaking, the newer AEDs appear to have comparable efficacy to the older agents and are perhaps better tolerated.

To date, among the newer generation agents, lamotrigine, oxcarbazepine, and topiramate have received FDA approval for use as monotherapy in patients with partial seizures. Phenobarbital and primidone are also useful in partial seizures, but sedation and cognitive adverse effects limit their utility. Felbamate, which has monotherapy approval, is effective but has been associated with some significant side effects. Interpretation of monotherapy trials with the newer AEDs can be daunting owing to the unique study designs and specific patient populations employed. Withholding an effective AED (i.e., giving placebo) in patients with epilepsy is generally considered unethical. For more information the reader is referred to published reviews.[50]

Primarily generalized seizures such as absence seizures may respond differently pharmacologically than other seizure types. Phenytoin, phenobarbital, and carbamazepine, although effective in GTC and partial seizures, are ineffective for absence seizures, and in some cases, can precipitate an increase in seizure frequency. Absence seizures are best treated with ethosuximide, valproic acid, and perhaps lamotrigine. For levetiracetam, topiramate, and zonisamide, additional data are needed to confirm efficacy. Oxcarbazepine, gabapentin, and tiagabine do not appear to be effective in treating absence seizures, and can worsen this condition

in some patients. If the patient has a combination of absence and other generalized or partial seizures, valproic acid or lamotrigine is the preferred first choice because they are effective for absence and other seizure types. If valproic acid is ineffective in treating a mixed seizure disorder that includes absence, ethosuximide could be used in combination with another AED.

The traditional treatment of tonic-clonic seizures is phenytoin; however, carbamazepine and valproic acid are increasingly used because these AEDs have a lower incidence of side effects with equal efficacy. Valproic acid generally is considered the drug of first choice for atonic seizures and for juvenile myoclonic epilepsy (JME). Lamotrigine and perhaps topiramate and zonisamide can be alternative agents for these seizure types. Levetiracetam has received FDA approval as adjunctive treatment of myoclonic seizures in patients with JME.

Results of a large, unblinded, randomized, controlled trial conducted in patients with new-onset generalized and unclassified epilepsy outpatients in the United Kingdom has helped to define the role of the newer generation drugs. These researchers found that for idiopathic generalized epilepsy, valproic acid was significantly better tolerated than topiramate and more efficacious than lamotrigine.[56]

Serum concentrations of the older AEDs should be viewed as a tool with which to optimize therapy for an individual patient, not as a therapeutic end point in itself. The serum concentration is a target that should be correlated with clinical response. The desired outcome is the cessation of seizures without side effects. Seizure control can occur before the "minimum" of the published therapeutic range is achieved, and side effects can appear before the "maximum" of the range is achieved. Some patients may need and tolerate concentrations beyond the maximum. The therapeutic range for AEDs can be different for different seizure types. Serum concentrations may need to be higher to control CP seizures than to control tonic-clonic seizures. Clinicians should define a therapeutic range for an individual patient above which there are side effects and below which the patient experiences seizures. Then serum levels can be useful to document lack of efficacy, loss of efficacy, noncompliance, and to determine how much room there is to increase a dose based on expected toxicity. Depending on the AED, serum levels can also be useful in patients with significant renal and/or hepatic disease, patients taking multiple drugs, and women who are pregnant or taking oral contraceptives (OCs). Therapeutic concentration ranges have not been clearly defined for some of the second generation AEDs.

THERAPEUTIC CONSIDERATIONS IN THE ELDERLY AND YOUNG

Use of AEDs in the elderlyand young can pose special challenges.[32] Avoidance of AEDs that interact with other medications that the elderly are often taking is of upmost importance. Many of the AEDs are inducers or inhibitors of the CYP450 system, which can adversely affect the drug level of concomitantly administered drugs. Hypoalbuminemia is common in the elderly, and can make monitoring and adjustment of serum drug levels of highly albumin-bound AEDs, such as phenytoin, valproic acid, and tiagabine, problematic. The elderly also experience body mass changes, such as an increase in fat to lean body mass or decrease in body water, which can affect the volume of distribution of some drugs, and therefore possibly the elimination half-life. In addition, declining renal and/or hepatic function can occur in the elderly, which can require a lower dose of the AED. Lastly, the pharmacodynamic response to AEDs can change with aging such that elderly patients may be more sensitive to various neurocognitive adverse effects. Also, elderly patients' seizures may be controlled at relatively lower total serum concentrations.

For neonates and infants, an increase in the total body water to fat ratio and a decrease in serum albumin and α-acid glycoprotein can result in volume of distribution changes that can affect the elimination half-life of the AEDs. In addition, newborns up to the age of 2 to 3 years display decreased efficiency in renal elimination, with newborns being the most affected. Hepatic activity is also reduced in this population. However, by age 2 to 3 years, hepatic activity is more robust than that seen in adults. Therefore, children require higher doses of many of the AEDs than adults, whereas neonates and infants require lower doses. Lastly, rapidly changing and sometimes inconsistent metabolism in the patient groups above makes therapeutic drug monitoring especially important even though the definition of therapeutic blood level is less certain in these patients than in adults.

THERAPEUTIC CONSIDERATIONS IN WOMEN (AND MEN)

Many hormones influence brain electrical excitability, and estrogen and progesterone may interact in complex ways to alter neuronal excitability and protein synthesis.[57] Estrogen has a slight pro-convulsant effect, whereas progesterone exerts a mild anticonvulsant effect. Estrogen has a mild inhibitory effect on GABA receptors, potentiates excitatory glutaminergic activity, and can promote the development of kindling. Progesterone has the opposite effect and appears to potentiate GABA receptor activity and reduce neuronal discharge rates. AEDs, especially hepatic metabolizing enzyme inducers, increase the metabolism of thesehormones and induce the production of sex hormone—binding globulin. This may lead to decreases in the unbound fraction of the hormone. Enzyme-inducing AEDs, including topiramate and oxcarbazepine at higher doses, can cause treatment failures in women taking OCs owing to induction of the metabolism of ethinyl estradiol and progestin. This may also be an issue with rufinamide, lamotrigine, and felbamate, all which have a small effect in decreasing the bioavailability of combination oral contraceptives (OCs). A supplemental form of birth control, in addition to OCs, is advised if breakthrough bleeding occurs. However medroxyprogesterone depot injection, copper intrauterine devices, and hormone-release intrauterine systems are not affected by AEDs. There are no data available on the efficacy of the emergency contraceptive pill in patients taking these AEDs, but it has been suggested that women use twice the normal dose of the postcoital pill.[58] Valproic acid, benzodiazepines, and most of the newer AEDs, such as gabapentin, levetiracetam, tiagabine, zonisamide, vigabatrin, and lacosamide, are not enzyme inducers and have not been implicated in reducing contraceptive effectiveness. Of note, OCs lower lamotrigine's serum level significantly and lower valproic acid's level about 20%.[32]

In some women, vulnerability to seizures is highest just before and during the menstrual flow (catamenial seizures) and at the time of ovulation. The increased susceptibility to seizures during those catamenial periods is associated with a slight increase of estrogen relative to progesterone. The risk of catamenial epilepsy is estimated at 12.5%, but it may be as high as 50% in women with epilepsy. This pattern of seizure exacerbation can also be related to progesterone withdrawal and changes in the estrogen-to-progesterone ratio. Conventional AEDs should be used as primary agents but intermittent supplementation with higher dose of AED or benzodiazepines should be considered. Acetazolamide also has been used during catamenial periods but with variable and limited success. Hormonal therapy with progestational agents, particularly cyclic natural progesterone therapy, may be effective. Reproductive endocrine disorders are common in women with epilepsy and include menstrual irregularity, infertility, sexual dysfunction, and possibly polycystic ovary syndrome (PCOS).[59] Potential mechanisms for

these disturbances include disruption of the hypothalamic-pituitary-adrenal (HPA) axis via seizure discharges in limbic structures and/or AEDs.[62] AEDs, particularly the enzyme-inducing agents (e.g., carbamazepine, phenytoin, and phenobarbital), also may affect HPA function by altering the metabolism of the neuroactive sex hormones, including testosterone. Although a causal relationship has not yet been established, there is an apparent increased incidence of PCOS in women with epilepsy who are receiving valproic acid.[59]

During pregnancy there may be increased maternal seizures, pregnancy complications, and adverse fetal outcome.[60] Approximately 25% to 30% of pregnant women have increased seizures, whereas seizures decrease in a similar number. However, the risk of seizures is significantly less if the patient has been seizure free 12 months prior to the pregnancy.[61] Increased seizure frequency may result from either a direct effect on seizure threshold or a reduction in AED concentration. An increase in clearance has been reported for phenytoin, carbamazepine, phenobarbital, ethosuximide, lamotrigine, oxcarbazepine, levetiracetam, topiramate, and clorazepate during pregnancy. Protein binding may also be reduced. The altered disposition of AEDs can begin as early as the first 10 weeks of pregnancy, and may require up to 4 weeks postpartum to normalize (longer for carbamazepine and phenobarbital than for phenytoin).

Women with epilepsy have a higher incidence of adverse pregnancy outcomes. Although the risk of congenital malformations is 4% to 6% (twice as high as in nonepileptic women), more than 90% of pregnancies in epileptic mothers have satisfactory outcomes. Older data, much of which included AED polytherapy, indicated that barbiturates and phenytoin may cause congenital heart malformations, orofacial clefts, and other malformations. From these data the risk of neural tube defect with valproic acid and carbamazepine has been estimated to be 0.5% to 1%, respectively, and appears to be related to drug exposure during gestational days 0 to 28. Other adverse pregnancy outcomes associated with maternal seizures, but not necessarily caused by AEDs, are growth, psychomotor, and mental retardation. Women with epilepsy are also more likely to have miscarriages, and 10% to 20% of infants are born with low birth weight. Updated practice parameters are available to aid in the counseling and management of pregnant women with epilepsy.[62–64]

Some teratogenic effects may be prevented by adequate folate intake; therefore, prenatal vitamins with folic acid (0.4–5 mg/day) should be given to any woman of child-bearing potential who is taking AEDs.[60] Higher folate doses should be used in women with a history of a previous pregnancy with a neural tube defect or taking valproic acid. Higher AED doses and serum concentrations, polytherapy, and a family history of birth defects appear to increase the teratogenic risk of AEDs. Deciding on the most effective single-drug treatment prior to conception is vitally important. New AEDs are reported to be less teratogenic, and animal reproductive toxicology studies appear to be favorable. At present, clinical data are still limited, and more experience is needed before the true risk (or lack thereof) can be determined. However, multiple registries worldwide are collecting prospective data on pregnancy outcomes in users of newer and older AEDs. To date, results indicate that valproic acid mono- as well as polytherapy is associated with a significantly higher rate of fetal malformations compared to the other AEDs, especially at doses greater than 1,400 mg/day.[65,66] Some AEDs can cause neonatal hemorrhagic disorder, which can be prevented by administrating 10 mg/day vitamin K orally to the mother during the last month of pregnancy and/or administering parenteral vitamin K to the newborn at delivery.[64]

Most AEDs pass into the breast milk, and concentrations are measureable in breastfeeding infants. In general, the degree of protein binding of a given AED allows for prediction of its concentration in breast milk. AEDs with less protein binding accumulate more in breast milk. Treatment with AEDs is not necessarily a reason to discourage breastfeeding. In fact, an argument could be made that since AEDs should rarely be discontinued abruptly, breastfeeding is a reasonable way to allow for a downward titration of a medication that the baby was exposed to for the past 9 months. Infants born to women taking any AED (particularly barbiturates or benzodiazepines) should be closely observed for signs of excess sedation, irritability, or poor feeding.[60]

The perimenopausal period can be associated with worsening of seizures. At menopause, seizures often improve in frequency, particularly in women with a catamenial seizure pattern. The effect of hormone replacement therapy on seizure control is still unclear, but clinicians should monitor for seizure exacerbation in women receiving supplemental estrogen. Exacerbation of seizures has been noted in postmenopausal women on lamotrigine taking hormone replacement therapy.[67] Data suggest that men with epilepsy have reduced fertility, and that carbamazepine, oxcarbazepine, and valproic acid are associated with sperm abnormalities in these men. In addition, valproic acid seems to cause testicular atrophy resulting in reduced testosterone volume.[68]

CLINICAL CONSIDERATIONS WITH SPECIFIC DRUGS

Tables 65–4 through 65–8 list specific data (including pharmacokinetics, adverse effects, AED interactions, metabolism, and dosing) for each of the commonly used AEDs. Below we summarize the pharmacology, advantages and disadvantages, and perspectives on the place in therapy of each AED.

Carbamazepine

Pharmacology and Mechanism of Action The exact mechanism by which carbamazepine suppresses seizure spread is obscure, however, it is believed to act primarily by enhancing fast inactivation of voltage-gated sodium channels. In addition, interaction with voltage-gated calcium and potassium channels might also contribute to its activity.[69]

Pharmacokinetics The absorption of carbamazepine from immediate-release tablets is slow and erratic because of its low water solubility. There is also large variability in the peak-to-trough concentrations of up to 40%. There is no first-pass metabolism. Food, especially fat, may enhance the bioavailability of carbamazepine. Carbamazepine suspension is absorbed faster than the tablets.[70] Controlled-release (Tegretol-XR) and sustained-release (Carbatrol) preparations are also available, and they are bioequivalent in twice-daily (every 12 hours) dosing to immediate-release carbamazepine dosed 4 times daily (every 6 hours). Compared with immediate-release carbamazepine, both these formulations have lower peaks and higher troughs, which may decrease side effects and improve seizure control. Carbatrol can improve QOL measurements compared to the immediate-release product.[71] Patients should be told to take Tegretol-XR with food and that the casing will be excreted in the feces. It cannot be broken or crushed. Tegretol-XR and Carbatrol appear to be bioequivalent; however, there is less variability in the absorption of Carbatrol.[70]

Carbamazepine is a neutral and highly lipophilic drug that is highly protein bound to α_1-acid glycoprotein and albumin. The major metabolite is carbamazepine-10,11-epoxide, which has anticonvulsant activity in animals and humans.[70] The formation of the 10,11-epoxide is influenced by concurrent use of other enzyme-inducing or enzyme-inhibiting drugs; thus the 10,11-epoxide concentration may change with the administration of other drugs (e.g., valproate and felbamate) with no change in parent carbamazepine concentration.[70]

TABLE 65-8 Antiepileptic Drugs Dosing and Target Serum Concentration Ranges

	Trade Name	Usual Initial Dose	Usual Maximum Daily Dose	Target Serum Concentration Range
Barbiturates				
Phenobarbital	Various	1–3 mg/kg/day (10–20 mg/kg LD)	180–300 mg	10–40 mcg/mL (43–172 μmol/L)
Primidone	Mysoline	100–125 mg/day	750–2,000 mg	5–10 mcg/mL (23-46 μmol/L)
Benzodiazepines				
Clonazepam	Klonopin	1.5 mg/day	20 mg	20–70 ng/mL (0.06–0.22 μmol/L)
Diazepam	Valium	PO: 4–40 mg IV: 5–10 mg	PO: 4–40 mg IV: 5–30 mg	100–1,000 ng/mL (0.4–3.5 μmol/L)
Lorazepam	Ativan	PO: 2–6 mg IV: 0.05 mg/kg IM: 0.05 mg/kg	PO: 10 mg IV: 0.05 mg/kg	10–30 ng/mL (31–93 μmol/L)
Hydantoin				
Phenytoin	Dilantin	PO: 3–5 mg/kg (200–400 mg) (15–20 mg/kg LD)	PO: 500–600 mg	Total: 10–20 mcg/mL (40–79 μmol/L) Unbound: 0.5–3 mcg/mL (2–12 μmol/L)
Succinimide				
Ethosuximide	Zarontin	500 mg/day	500–2,000 mg	40–100 mcg/mL (282–708 μmol/L)
Other				
Carbamazepine	Tegretol	400 mg/day	400–2,400 mg	4–12 mcg/mL (17–51 μmol/L)
Felbamate	Felbatol	1,200 mg/day	3,600 mg	30-60 mcg/mL (126–252 μmol/L)
Gabapentin	Neurontin	900 mg/day	4,800 mg	2–20 mcg/mL (12–117 μmol/L)
Lacosamide	Vimpat	100 mg/day	400 mg	Not defined
Lamotrigine	Lamictal	25 mg every other day if on VPA; 25–50 mg/day if not on VPA	100–150 mg if on VPA; 300–500 mg if not on VPA	4–20 mcg/mL (16–78 μmol/L)
Levetiracetam	Keppra Keppra XR	500–1,000 mg/day	3,000–4,000 mg	12-46 mcg/mL (70–270 μmol/L)
Oxcarbazepine	Trileptal	300–600 mg/day	2,400–3,000 mg	3-35 mcg/mL (MHD) (12–139 μmol/L)
Pregabalin	Lyrica	150 mg/day	600 mg	Not defined
Rufinamide	Banzel	400–800 mg/day	3,200 mg	Not defined
Tiagabine	Gabitril	4–8 mg/day	80 mg	0.02–0.2 mcg/mL (0.05–0.5 μmol/L)
Topiramate	Topamax	25–50 mg/day	200–1,000 mg	5-20 mcg/mL (15–59 μmol/L)
Valproic acid	Depakene Depakene SR Depakote Depakote ER Depacon	15 mg/kg (500–1,000 mg)	60 mg/kg (3,000–5,000 mg)	50–100 mcg/mL (347–693 μmol/L)
Vigabatrin	Sabril	1,000 mg/day	3,000 mg	0.8–36 mcg/mL (6–279 μmol/L)
Zonisamide	Zonegran	100–200 mg/day	600 mg	10–40 mcg/mL (47–188 μmol/L)

IM, intramuscular; LD, loading does; MHD, 10-monohydroxy- derivative; PO, orally; VPA, valproic acid.
Data from Patsalos et al.,[32] Halford and Lapointe,[33] Cada et al.,[34] and Sabril [package insert].[35]

Carbamazepine induces its own metabolism (autoinduction), thereby decreasing its half-life after chronic therapy.[70] The presence of enzyme-inducing drugs reduces the half-life even more. The enzyme-induction effect begins within 3 to 5 days of starting therapy and takes 21 to 28 days to complete. Therefore, it is possible to achieve initial concentrations that are within the therapeutic range but have concentrations fall despite continued therapy and good compliance. Some patients who respond well to initial therapy may be labeled refractory or noncompliant if the autoinduction phenomenon is not considered. The autoinduction reverses rapidly if carbamazepine is discontinued. Carbamazepine also displays diurnal variation in its serum level with evening levels lower than morning levels.

Adverse Effects Carbamazepine side effects can parallel the rise and decline of serum concentrations daily. Neurosensory side effects (e.g., diplopia, blurred vision, nystagmus, ataxia, unsteadiness, dizziness, and headache) are the most common (35%–50% of patients). These side effects are more common during initiation of therapy and can dissipate with continued treatment. Carbamazepine can also cause nausea, which can be caused by a local effect of the drug on the GI tract, in which case food may help, or be caused by an effect on the brainstem, which may ultimately require discontinuation of the drug. Dosage manipulation, including the use of the controlled- or sustained-release preparations, should be tried before the patient is considered to be intolerant of carbamazepine. Carbamazepine can cause hyponatremia, the incidence of which increases with age, however, its occurrence is lower than that seen with oxcarbazepine. Periodic determinations of serum sodium concentration are recommended, especially in the elderly.[70]

Leukopenia is the most common hematologic side effect, with an incidence as high as 10%. It usually is transient, even when the drug is continued, and can be caused by a redistribution of white blood cells (WBCs) rather than a decrease in their production. In about 2% of patients, leukopenia is persistent, but even patients with WBC counts of 3,000/mm^3 (3×10^9/L) or less do not seem to have an increased incidence of infection. A clinical guide is to continue carbamazepine therapy unless the WBC count drops to less than 2,500/mm^3 (2.5×10^9/L) and the absolute neutrophil count drops to less than 1,000/mm^3 (1×10^9/L).[70]

Drug Interactions Because of concentration-dependent efficacy and side effects, drug interactions with carbamazepine often are very significant. Drugs that inhibit CYP3A4 potentially may increase carbamazepine serum concentrations. Carbamazepine can induce the metabolism of other drugs.

Dosing and Administration The variable contributions of the 10,11-epoxide metabolite and free-carbamazepine concentrations have restricted a precise definition of the therapeutic range.

Loading doses of carbamazepine are indicated only for critically ill patients. During dosage titration, it must be remembered that carbamazepine clearance increases with time. Doses may be started at one-fourth to one-third the anticipated maintenance dose and increased every 2 to 3 weeks. Because of the auto- and heteroinduction of carbamazepine metabolism, it is necessary to administer the drug two to four times per day. Carbamazepine tablets should not be stored in places where they would be exposed to high heat and high humidity.[70]

Advantages Carbamazepine has been well studied. Oral solid and liquid dosage forms are available. The oral solid dosage form is available as an immediate-release tablet, as a sustained-release capsule, and a controlled-release tablet. The sustained- and controlled-release dosage forms allow for twice-daily dosing to reduce the peak-to-trough fluctuations. Compared with other first-generation AEDs, carbamazepine causes minimal cognitive impairment.

Disadvantages Carbamazepine has an active metabolite that can contribute to efficacy and toxicity. Other drugs can alter the concentration of this metabolite without changing the concentration of the parent carbamazepine. It induces its own metabolism, which complicates dosage titration. It also induces the metabolism of other medications, and other drugs may interact with it and/or its active metabolite. There is no parenteral formulation. There are clinically meaningful CNS side effects including sedation and nausea. One prospective study, however, found fewer side effects with the sustained-release formulation compared to the immediate-release formulation.[71] When ingested during the first trimester of pregnancy, carbamazepine has been associated with a 1% risk of spina bifida. Chronic carbamazepine use has also been associated with decreases in bone mineral density and 25-hydoxy(OH) vitamin D. The generic formulations of immediate-release tablets have been associated with breakthrough seizures when brands have been switched.

Place in Therapy Carbamazepine is considered a first-line therapy for patients with newly diagnosed partial seizures and for patients with primary generalized convulsive seizures who are not in an emergent situation.

Ethosuximide

Pharmacology and Mechanism of Action Ethosuximide is believed to exert its primary action through inhibition of T-type calcium channels.[69]

Pharmacokinetics Metabolism occurs in the liver by hydroxylation, and the metabolites are believed to be inactive. There is some evidence of nonlinear pharmacokinetics at higher concentrations.

Adverse Effects The most frequently reported side effects are nausea and vomiting (up to 40%), which may be minimized by administration of smaller doses and more frequent dosing.[72]

Drug Interactions Because ethosuximide is not protein bound, displacement interactions do not occur. Valproic acid may inhibit the metabolism of ethosuximide, but only if the metabolism of ethosuximide is near saturation.[73]

Dosing and Administration A loading dose is not required. Titration over 1to 2 weeks to maintenance doses of 20 mg/kg per day usually results in therapeutic concentrations. Data suggest that patients can be managed successfully on once-a-day therapy; however, gastrointestinal (GI) distress appears to be dose related, and the total daily dose is usually divided into two equal doses.[70]

Advantages This drug is very effective in the treatment of absence seizures. It is generally well tolerated and has few pharmacokinetic interactions.

Disadvantages Ethosuximide has a very narrow spectrum of activity.

Place in Therapy Ethosuximide is still a first-line treatment for absence seizures.

Felbamate

Pharmacology and Mechanism of Action At therapeutic doses, felbamate appears to act by blocking *N*-methyl-D-aspartate (NMDA) synaptic responses and by modulating $GABA_A$ receptors. At higher doses it may modulate sodium channels and inhibit high-voltage activated calcium channels.[69]

Pharmacokinetics Felbamate is rapidly and well absorbed. The absorption is unaffected by food or antacids. Approximately 40% to 50% of a dose of felbamate is metabolized by hydroxylation and conjugation pathways in the liver, and the remainder is excreted unchanged in the urine. It displays linear pharmacokinetics.[74]

Adverse Effects The most frequently reported side effects prior to marketing were anorexia, weight loss, insomnia, nausea, and headache (sometimes severe). Anorexia and weight loss may be especially problematic in children and in patients with diminished caloric intake. After marketing, felbamate was found to be associated with aplastic anemia and acute liver failure. The onset was between 68 and 354 days of therapy. The approximate rate of occurrence of aplastic anemia is 1 in 3,000 and of hepatitis is 1 in 10,000. Data suggest a possible increased risk for aplastic anemia in patients, especially women, with a history of cytopenia, AED allergy or significant toxicity, viral infection, and/or immunologic problems.[24,25,75]

Drug Interactions Felbamate can induce or inhibit the metabolism of the older AEDs. Interactions between warfarin and felbamate have also been reported.[74]

Dosing and Administration The initial starting dose of felbamate is increased at 2-week intervals.

Advantages Felbamate has a broad spectrum of activity and a unique mechanism of action. It is approved for treating atonic seizures in patients with the Lennox—Gastaut syndrome and is also effective in treating patients with partial seizures.

Disadvantages The use of felbamate is limited by the association with aplastic anemia and hepatotoxicity, as well as multiple drug interactions.

Place in Therapy It should be reserved for patients not responding to other AEDs.

Gabapentin

Pharmacology and Mechanism of Action Gabapentin was designed to be a GABA agonist but does not react at the GABA receptor, alter GABA uptake, or interfere with GABA transaminase. Gabapentin appears to bind to an amino acid carrier protein and to act at a unique receptor. It inhibits high-voltage activated calcium channels.[69] It elevates human brain GABA levels, possibly via alterations in GABA synthesis or reversal of the neuronal GABA transporter, resulting in nonvesicular release of GABA.[76]

Pharmacokinetics Gabapentin is a substrate of the L-amino acid carrier protein in the gut (system L) and in the CNS.[77] This carrier protein transports the drug across the gut membrane by an active process. The binding of gabapentin to this system is saturable, and gabapentin therefore displays dose-dependent bioavailability that appears to vary considerably between individuals.[78] Food, including protein-rich meals, does not appear to interfere with gabapentin oral absorption.[79] Concentrations in human CSF are 5% to 35% of plasma levels, and tissue concentrations are approximately 80% of plasma levels.

Because gabapentin is eliminated exclusively by the kidneys, dosage adjustments are necessary in patients with significantly impaired renal function.[80]

Adverse Effects Fatigue, somnolence, dizziness, and ataxia are the most frequently reported side effects. Aggressive behavior has been reported in children.[81] The CNS effects of gabapentin are generally less than those of traditional AEDs. A withdrawal reaction characterized by anxiety, insomnia, nausea, sweating, and increased pain has also been reported with abrupt discontinuation in patients taking it for pain.

Drug Interactions Gabapentin does not induce or inhibit liver enzymes; therefore, drug interactions are not likely to occur. There is a 10% reduction in the clearance of gabapentin in patients taking cimetidine and a 20% reduction in the bioavailability if aluminum antacids are taken simultaneously with gabapentin. These interactions are unlikely to be clinically significant.

Dosing and Administration Typical starting doses of gabapentin are 300 mg at bedtime on the first day, increasing to 900 mg/day over 3 days. Faster titration rates (e.g., starting at 300–900 mg 3 times daily) have been well tolerated.[82] Data suggest gabapentin should be given at least 4 times a day when the total daily dose is 3,600 mg or greater.[73] It does not appear to be absorbed rectally. Patients with end-stage renal disease maintained on hemodialysis should receive an initial 300- to 400-mg dose with 200 to 300 mg gabapentin given after every 4 hours of hemodialysis.[80]

Advantages Gabapentin has multiple mechanisms of action and is mechanistically different from first-generation AEDs. It is not metabolized and is excreted unchanged by the kidney. It has a broad therapeutic index with minimal CNS adverse effects and few drug interactions. Doses can be escalated rapidly.

Disadvantages Gabapentin is absorbed by an active process that saturates at higher doses. This may require more frequent daily dosing for patients who need doses greater than 3,600 mg/day. Doses exceeding the 3,600 mg/day maximum listed in the package insert may be required in some patients to achieve seizure remission. There is no parenteral formulation.

Place in Therapy Gabapentin is a second-line agent for patients with partial seizures who have failed initial treatment. In addition, although monotherapy has no proven efficacy in previously diagnosed refractory patients, it may have a role in patients with less severe seizure disorders, such as new-onset partial epilepsy, particularly in the elderly. Gabapentin also has been shown to be useful for chronic pain and other nonepileptic conditions.

Lacosamide

Pharmacology and Mechanism of Action Lacosamide is a functionalized amino acid with unknown mechanism of action, but two mechanisms are suggested.[33] It selectively enhances slow inactivation of voltage-gated sodium channels, resulting in stabilization of hyperexcitable neuronal membranes and inhibition of repetitive neuronal firings. In addition, it binds to collapsin response mediator protein (CRMP-2), a phosphoprotein mainly expressed in the CNS, and it is involved in neuronal differentiation and control of axonal outgrowth. The role of CRMP-2 binding in seizure control is unknown.

Pharmacokinetics Lacosamide is rapidly and almost completely absorbed after oral administration, and food does not affect its bioavailability. There is a linear relationship between daily doses and serum concentrations up to 800 mg/day. No dosage adjustment is necessary in children or the elderly. Moderate hepatic and renal impairment have both been shown to increase systemic drug exposure up to approximately 40%.[33]

Adverse Effects The most frequent side effects of lacosamide are dose related, including dizziness, nausea, diplopia, abnormal coordination, ataxia, vomiting, and nystagmus. The drug can also cause a small increase in median PR interval (5–9 msec) on the ECG.

Drug Interactions The blood level of lacosamide is decreased by approximately 15% to 20% by enzyme-inducing AEDs.[33] It is a substrate of CYP2C19; however, there are no known drug interactions between lacosamide and drugs metabolized by CYP2C19. The drug does not appear to affect the serum concentration of OCs containing ethinyl estradiol and levonorgesterol.[33]

Dosing and Administration The starting dose is 100 mg/day in two divided doses, with dose increase by 100 mg/day every week until a daily dose of 200 to 400 mg has been reached. Studies have shown that a dose of 600 mg daily may be efficacious for some patients, but at the expense of more CNS side effects.

Advantages There is an intravenous form of lacosamide available for short-term replacement that appears to be safe, well tolerated, and easy to administer. It does not affect the serum level of other AEDs, and its serum level is minimally affected by enzyme-inducing AEDs. It has novel mechanism(s) of action.

Disadvantages Lacosamide is a controlled substance class V.

Place in Therapy It is a potent second-line agent that should be considered in those patients who have failed first-line AEDs.

Lamotrigine

Pharmacology and Mechanism of Action A primary mechanism of action for lamotrigine appears to be inhibition of voltage-dependent sodium channels; however, it also inhibits high voltage-activated calcium channels and attenuates release of glutamate and to a lesser extent, GABA and dopamine.[69]

Pharmacokinetics Lamotrigine is completely and rapidly absorbed, with a bioavailability of 98%. Food does not significantly affect absorption. It is also absorbed following rectal administration, but the bioavailability is approximately 50% of that of oral dosage forms. Lamotrigine clearance is higher in children and lower in the elderly compared with young adults. There are only modest differences in the pharmacokinetics of lamotrigine in the elderly versus younger subjects. Hepatic disease, depending on severity, can influence lamotrigine pharmacokinetics. Approximately 17% of a lamotrigine dose can be removed by hemodialysis, with the half-life being reduced to approximately 13 hours. For patients on dialysis, the half-life is much more prolonged between dialyses (57.4 hours).[84] The half-life is prolonged in patients with renal failure.

Adverse Effects The most frequently reported side effects of lamotrigine include diplopia, drowsiness, ataxia, and headache.[85] Adverse effects are more common when lamotrigine is given in combination with other AEDs (e.g., diplopia when given concomitantly with carbamazepine or tremor with valproic acid) compared with monotherapy, and they can be pharmacodynamic in nature. Lamotrigine can cause rash, which usually appears in the first 3 to 4 weeks of therapy. Patients who have developed a rash with another AED are more likely to develop a rash with lamotrigine.[86] The rash typically is generalized, erythematous, and morbilliform. However, a Stevens—Johnson reaction also has been reported. Some rashes, especially those which develop early, can necessitate the withdrawal of lamotrigine.[87] Risk factors for the emergence of more serious rashes appear to be concomitant use of valproic acid and situations where high initial doses or rapid dosage escalation is used. Data from several European monotherapy trials suggest that when dosed appropriately, the incidence of rash from lamotrigine is similar to that of older agents such as carbamazepine and phenytoin. The incidence is higher in children than in adults.

Drug Interactions Lamotrigine does not inhibit liver enzymes and has a low potential for pharmacokinetic interactions with other drugs. It has been found to decrease the bioavailability of the progesterone component (levonorgestrel) of a combination OC by 19%. The clinical relevance of this interaction has not been determined.[88]

Concomitant treatment with OCs can lead to a reduction in the serum concentrations of lamotrigine because of an induction of lamotrigine glucuronidation by ethinyl estradiol.[89] In addition lamotrigine serum levels can significantly increase during the week off OC treatment in some patients.[89]

Valproic acid substantially inhibits the metabolism of lamotrigine, with maximal inhibition occurring at valproic acid doses and serum concentrations of 500 mg/day and 40 to 50 mcg/mL (280–350 μmol/L), respectively.[85] A pharmacodynamic interaction can occur with concurrent carbamazepine therapy, causing an increase in CNS side effects.

Dosing and Administration In patients who are taking enzyme-inducing drugs, lamotrigine can be started more rapidly than in patients receiving valproic acid. The maintenance doses are also different. Managing dosing is critical owing to the relationship between rash, concomitant valproic acid treatment, and the dose escalation rate. Removal of inducers from a lamotrigine regimen may necessitate decreases in lamotrigine dose, whereas removal of valproic acid can necessitate an increase in the lamotrigine dose. A dispersible and oral disintegrating tablet are available for patients who cannot swallow an oral solid tablet.

Advantages Lamotrigine is potentially a broad-spectrum AED, having efficacy in partial seizures and several types of generalized seizures. Pediatric dosage forms are available as a chewable dispersable tablet and an oral disintegrating tablet. It neither induces nor inhibits the metabolism of other AEDs. Lamotrigine has linear pharmacokinetics and is not highly protein bound. It is generally well tolerated in both children and elderly patients and does not cause weight gain.

Disadvantages Lamotrigine is associated with rash, especially in patients who start at a high dose, have rapid dose escalation, and/or are taking concurrent valproic acid. Therefore, the initial doses must be low (especially if the patient is on valproic acid) and escalated slowly to maximize safety. There is no parenteral dosage form.

Place in Therapy Lamotrigine is useful as both adjunctive treatment in patients with partial seizures and as monotherapy. Lamotrigine monotherapy appears to have comparable effectiveness with more traditional AEDs such as carbamazepine and phenytoin. In addition, it may be a useful alternative for primary generalized seizure types such as absence and as adjunctive therapy for primary GTC seizures, the latter of which is an approved indication.

Levetiracetam

Pharmacology and Mechanism of Action Levetiracetam is chemically unrelated to other AEDs. Although the mechanism of action of levetiracetam has yet to be delineated, it is known that this drug is not active in the classic models used to test AEDs. The drug binds in the brain to the synaptic vesicle protein SV2A, which is believed to be important in its activity.[90] This agent may have a unique mechanism of action. Limited animal data suggest that levetiracetam may have *antiepileptogenic effects*, meaning that it may prevent the development of epilepsy under certain circumstances, however confirmation of this research is needed. [91]

Pharmacokinetics Absorption of levetiracetam is rapid and complete following oral administration, and it is not significantly affected by food or enteral nutrition formulas.[92] Renal elimination of unchanged parent drug accounts for the majority of clearance (66%), with the remainder being metabolized via nonhepatic enzymatic hydrolysis to inactive metabolites.[93] This pathway involves neither the CYP450 or UGT isozyme systems. Because it is eliminated renally, clinicians should anticipate age-related reductions in clearance in elderly patients. Conversely, levetiracetam clearance appears to be approximately 40% higher in children than in adults. In addition, patients with severe liver cirrhosis should initially receive one-half the recommended starting dose because of a 57% decrease in clearance.[94] Levetiracetam is excreted into breast milk in potentially clinically important amounts.[95] Data are sparse regarding serum concentration—effect relationships, so the role of therapeutic drug level monitoring remains unclear.

Adverse Effects Adverse effects appear to be modest, with sedation, fatigue, and coordination difficulties being the most common CNS effects. In children and young adults, agitation, irritability or somnolence/lethargy are the most frequently reported CNS side effects.[96] The mechanism underlying these effects is unknown. Formal studies evaluating the cognitive effects of this medication have not yet been conducted.

Drug Interactions Levetiracetam neither inhibits nor induces the CYP450, UGT, or epoxide hydrolase enzyme systems, and in vitro data predict a low potential for pharmacokinetic interactions. It does not appear to interact with other AEDs, warfarin, digoxin, or oral contraceptive drugs.[97,98]

Dosing and Administration Levetiracetam is available orally and parenterally, the latter for maintenance dosing only. The intravenous (IV) product has not been tested for intramuscular (IM) use, and therefore, should not be administered IM. Typically the initial dose is given twice daily, with dosage increments every 2 weeks. To minimize CNS side effects, dosing may be initiated at one-half this rate. The IV formulation should be given at the same frequency and dose as the oral product. Although not FDA approved, the oral dose of levetiracetam has been titrated up rapidly to 3,000 mg in 3 days in some intractable seizure patients with improvement seen after day 2.[99]

Advantages Levetiracetam is felt to have a novel, although unknown, mechanism of action. It has linear pharmacokinetics and is not metabolized by the cytochrome P450 system. No significant drug interactions, including with OCs, have been reported. Initial doses may be effective. The drug appears to be well tolerated, with transient sedation being the most troublesome adverse effect.

Disadvantages Dose adjustments are needed for patients with decreased renal function, and slower dose escalation may be needed to avoid CNS adverse effects. Behavioral problems can limit therapy in some patients.

Place in Therapy Levetiracetam is indicated for patients with partial seizures who have failed initial therapy. Its role as monotherapy for partial seizures remains to be clarified. It is approved for adjunctive treatment of myoclonic seizures in patients with JME and as adjunctive treatment of primarily generalized seizures in patients with idiopathic generalized epilepsy.

Oxcarbazepine

Pharmacology and Mechanism of Action Oxcarbazepine, which is structurally related to carbamazepine, is a prodrug that is rapidly converted to the active 10-monohydoxy derivative (MHD). The mechanism of action of oxcarbazepine is similar to that of carbamazepine. Oxcarbazepine and MHD block voltage-sensitive sodium channels, modulate the voltage-activated calcium currents, and increase potassium conductance. Interestingly, however, oxcarbazepine can display differing affinities for both sodium channels and $Ca2^+$ channels compared with older drugs such as carbamazepine.[100] Whereas carbamazepine may modulate L-type $Ca2^+$ channels, oxcarbazepine appears to modulate N- and P-type $Ca2^+$ channels.[101] Whether these differences lead to differing patterns of clinical effectiveness is uncertain. It has no significant interactions with neurotransmitters or modulation of receptor sites.

Pharmacokinetics Oxcarbazepine is absorbed completely, and MHD is inactivated by glucuronide conjugation and eliminated by the kidneys.[102] Oxcarbazepine and its active metabolite do

not undergo autoinduction. The relationship between dose and serum concentration is linear. Children 2 to 6 years of age need larger doses to achieve the same serum concentration, suggesting a more rapid clearance. The maximal drug concentration (C_{max}) and bio-availability of MHD in elderly volunteers were higher than in younger volunteers, and the elimination rate was slower, possibly reflecting decreased renal elimination. Patients with significant renal impairment may require a dosage reduction.

Adverse Effects Oxcarbazepine was marketed in more than 50 countries prior to approval in the United States. In U.S. clinical trials the most frequently reported adverse events were dizziness, nausea, headache, diarrhea, vomiting, upper respiratory tract infections, constipation, dyspepsia, ataxia, and nervousness. In comparative trials, oxcarbazepine generally caused fewer side effects than phenytoin, valproic acid, or carbamazepine. Dizziness may be more common in elderly patients than in young adults. CNS adverse effects appear to be far more common at doses greater than 1,200 mg/day. Hyponatremia, defined as a plasma sodium concentration of less than 125 mmol/L, has been reported in up to 25% of patients taking oxcarbazepine and occurs more often in elderly patients. Clinicians should be particularly watchful in patients receiving concomitant sodium-depleting drugs such as diuretics. Hyponatremia appears to occur less frequently in children. Clinicians should consider monitoring serum sodium levels following the initiation of oxcarbazepine, and they should instruct patients regarding the symptoms of hyponatremia. Approximately 25% to 30% of patients who develop a rash with carbamazepine will experience a similar reaction with oxcarbazepine.[24,25,75] The tolerability of oxcarbazepine has not been compared with that of extended-release formulations of carbamazepine that have lower peaks and potentially fewer side effects than immediate-release carbamazepine formulations.

Drug Interactions Oxcarbazepine decreases the bioavailability of ethinyl estradiol and levonorgestrel.[103] Women concurrently taking OCs should be counseled about the potential for contraceptive failure. Unlike carbamazepine, there are no interactions between cimetidine, erythromycin, or warfarin and oxcarbazepine. The administration of oxcarbazepine in doses greater than 1,200 mg with phenytoin has resulted in a 40% increase in the concentration of phenytoin, consistent with inhibition of CYP450 2C19. Oxcarbazepine treatment may modestly reduce lamotrigine serum concentrations, suggesting induction of UGT isozymes.[104]

The replacement of carbamazepine with oxcarbazepine may result in a drug interaction because an enzyme-inducing drug is being removed.

Dosing and Administration Doses and titration schedules differ regarding whether the drug is used for mono- or adjunctive therapy in adults vs children. Although not FDA approved, doses up to 60 mg/kg/day have been used in infants and children younger than 4 years of age to successfully control partial-onset seizures.[105] In patients being converted from carbamazepine, the typical maintenance dose of oxcarbazepine is 1.5 times the carbamazepine dose or less, if patients are on large doses of carbamazepine, due to autoinduction of carbamazepine but not oxcarbazepine.

Advantages The efficacy of oxcarbazepine is comparable with that of carbamazepine, phenytoin, and valproic acid. It may be better tolerated than phenytoin as monotherapy and therefore, less likely to be discontinued.[106] There is broad international experience with this drug.

Disadvantages About 30% of patients who have experienced a rash with carbamazepine have a cross-reaction with oxcarbazepine. There are more reports of hyponatremia with oxcarbazepine, especially in patients at risk. Replacing carbamazepine with oxcarbazepine can result in interactions owing to the removal of an enzyme inducer. Enzyme-inducing drugs can increase the clearance of MHD.

Place in Therapy Oxcarbazepine is indicated for use as monotherapy or adjunctive therapy in the treatment of partial seizures in adults and children as young as 4 years of age. It is also a potential first-line drug for patients with primary generalized convulsive seizures. Oxcarbazepine may also be effective in patients not demonstrating a response to carbamazepine.

Phenobarbital

Pharmacology and Mechanism of Action Phenobarbital may elevate seizure threshold by interacting with GABA receptors to facilitate intrinsic chloride channel function, by blocking high voltage-activated calcium channels, and by blocking α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate receptors.[69]

Pharmacokinetics Phenobarbital is absorbed rapidly and completely regardless of whether it is given orally, intramuscularly, or rectally.[73] It penetrates the brain at a rate comparable with that of phenytoin, and peak concentrations are achieved 3 to 20 minutes after an IV dose.

Drugs affecting liver enzymes can alter phenobarbital metabolism, but phenobarbital clearance is not affected by liver blood flow. The elimination of phenobarbital is linear. Because tubular reabsorption of phenobarbital is pH dependent, the amount excreted renally can be increased by giving diuretics and urinary alkalinizers.[73] Clearance decreases in the elderly.[107]

Adverse Effects CNS side effects are the primary factors limiting the use of phenobarbital. Tolerance usually develops to initial complaints of fatigue, drowsiness, sedation, and depression. In children, paradoxically, the primary side effect is hyperactivity. It may also cause porphyria and rash, including serious rashes such as Stevens—Johnson syndrome.[108]

Drug Interactions Phenobarbital is a potent enzyme inducer and can increase the elimination of any drug metabolized by CYP450- or UGT-mediated metabolism. Cimetidine and chloramphenicol inhibit phenobarbital metabolism, necessitating a decrease in dose. Ethanol increases the metabolism of phenobarbital.[73]

Dosing and Administration In nonacute situations, phenobarbital should be started in low doses and titrated upward. The dose-concentration relationship is linear. Because the half-life of phenobarbital is long, doses can be given once daily, and bedtime dosing may minimize CNS depression.

Advantages Phenobarbital has linear and predictable pharmacokinetics. Multiple dosage forms (e.g., oral solid, oral liquid, IM, and IV) are available, and it is the most inexpensive AED.

Disadvantages Phenobarbital has significant side effects, including delayed intellectual development and hyperactivity in children and significant cognitive impairment in adults. It is an enzyme inducer and interacts with many other drugs metabolized by the cytochrome P450 system. Phenobarbital has a very long half-life, and dosage adjustments should not be made more often than every 2 to 3 weeks. The parenteral product contains 67% to 75% propylene glycol and 10% alcohol, which can result in significant respiratory depression and hypotension if infused too rapidly.

Place in Therapy Phenobarbital is the drug of choice for neonatal seizures but in other situations is reserved for patients who have failed therapy with other AEDs. It may be useful given IV in refractory status epilepticus.

Phenytoin

Pharmacology and Mechanism of Action The primary mechanism of action of phenytoin is believed to be its ability to inhibit voltage-dependent sodium channels.[69]

Pharmacokinetics The pharmacokinetics of phenytoin are complex. For a more in-depth understanding, the reader is referred to a more extensive review.[109] The oral absorption of phenytoin is almost complete. Dissolution is the rate-limiting step, and absorption may be saturable at higher doses, such as those used for oral loading. Absorption following IM administration of phenytoin is erratic and delayed, and IM injections are painful; however, IM absorption following fosphenytoin is rapid and well tolerated.

Phenytoin enters the brain rapidly and is redistributed to other body tissues, including breast milk and the placenta. Phenytoin competes for albumin sites with other highly protein-bound drugs. It is essential to know the patient's serum albumin level in interpreting the serum concentrations of phenytoin.[110] Patients with significant renal dysfunction will have altered phenytoin protein binding. Obesity increases the volume of distribution.

Phenytoin is metabolized in the liver by parahydroxylation. The major isoforms responsible for the metabolism of phenytoin are CYP2C9 and CYP2C19; the former displays polymorphism, which may affect the response to phenytoin.[69] Phenytoin displays Michaelis—Menton pharmacokinetics, and the metabolism of phenytoin saturates at doses used clinically. The clinical importance of this is that a small change in dose can result in a disproportionally large increase in serum concentrations, potentially leading to toxicity. In some patients the metabolism of phenytoin can saturate even at low serum concentrations within the therapeutic range. The long held belief that the metabolism of phenytoin decreases with age in adults has recently been challenged.[111]

Adverse Effects When phenytoin is initiated, the CNS depressant effects include lethargy, fatigue, incoordination, blurred vision, higher cortical dysfunction, and drowsiness. These effects usually are transient and can be minimized by slow dosage titration. At very high concentrations of greater than 50 mcg/mL (200 μmol/L), phenytoin can exacerbate seizures.

It is unclear whether the chronic side effects of phenytoin are concentration or duration dependent. One of the more common chronic side effects is gingival hyperplasia. Good oral hygiene can minimize gingival hyperplasia and should be encouraged. Other chronic effects include vitamin D deficiency, osteomalacia, carbohydrate intolerance, immunologic disturbances, hypothyroidism, and peripheral neuropathy. Phenytoin is associated with rare hypersensitivity or idiosyncratic reactions resulting in rashes, Stevens—Johnson syndrome, pseudolymphoma, bone marrow suppression, lupus-like reactions, and hepatitis.[112]

Drug Interactions Phenytoin is associated with numerous drug interactions involving altered absorption, metabolism, and protein binding that can enhance or reduce its effects. It is an inducer of both CYP450 and UGT isozymes. The absorption of phenytoin can be increased or decreased with the administration of food depending on the composition of the meal. The bioavailability of phenytoin suspension can be decreased in patients receiving continuous enteral nutrient tube feedings. However, a single-dose study of simultaneous administration of enteral feeding found no difference in phenytoin bioavailability, suggesting that the mechanism was something other than physical contact.[109]

Phenytoin decreases folic acid absorption. Replacement of folic acid can reduce phenytoin concentration and result in loss of efficacy.[109]

Dosing and Administration Four oral dosage forms are available, and changing dosage forms can lead to changes in phenytoin serum concentrations. Whether or not a dosage form uses the parent drug or salt form should be considered when changing from one dosage form to another. One hundred milligrams of phenytoin acid is equal to 92 mg of phenytoin sodium. Phenytoin capsules are designated as immediate-release or extended-release. Only the extended-release capsules should be used in once-daily dosing. Particle size rather than formulation may determine the rate of absorption.

If oral administration is not feasible, IV administration of phenytoin is preferred, as IM administration can cause tissue necrosis. Fosphenytoin is a prodrug for phenytoin and is available as a parenteral dosage form. Fosphenytoin is ordered in phenytoin equivalents (PE), the actual dose of phenytoin acid desired. It is very water-soluble and is converted rapidly to phenytoin systemically. Fosphenytoin can be given rapidly intravenously and intramuscularly with reliable absorption and minimal pain. It is significantly better tolerated than phenytoin.

Because of saturable absorption, an oral loading dose, such as 20 mg/kg, should be divided into four equal doses and given at 6-hour intervals. Subsequent dosage adjustments should be done cautiously owing to its nonlinear elimination. One author has suggested that if the serum concentration is less than 7 mcg/mL (28 μmol/L), the daily dose should be increased by 100 mg; if the serum concentration is between 7 and 12 mcg/mL (28 and 48 μmol/L), the daily dose can be increased by 50 mg; and if the serum concentration is greater than 12 mcg/mL (48 μmol/L), the daily dose can be increased by 30 mg or less. These increases are reported to result in less than 10% of patients achieving a phenytoin serum concentration greater than 25 mcg/mL (99 μmol/L).[113]

Advantages After more than 65 years, its risk-to-benefit ratio is well established. It is available in oral solid, oral liquid, extended-release oral solid, and parenteral (phenytoin and fosphenytoin) dosage forms, allowing flexibility in dosing and use in emergent situations. In some patients, the extended-release dosage form can be given once a day with good seizure control.

Disadvantages Phenytoin displays Michaels—Menton pharmacokinetics, meaning that the metabolism saturates at doses given clinically thus complicating dose titration. Also, phenytoin is an inducer of cytochrome P450 isozymes, is metabolized by cytochrome P450 enzymes, and is highly protein bound. Therefore, many drug interactions are associated with coadministration of this agent. It also has multiple significant adverse effects.

Place in Therapy Phenytoin has long been a first-line AED for primary generalized convulsive and partial seizures. However, its place in therapy may be reevaluated as more experience is gained with newer AEDs.

Pregabalin

Pharmacology and Mechanism of Action Pregabalin's mechanism of action is unknown, however, it is proposed that its binding to the subunit of the voltage-gated calcium channel may be responsible for a large part of its activity. This binding results in a decrease in the release of several excitatory neurotransmitters including glutamate, noradrenaline, substance P, and calcitonin gene-related peptide.[114]

Pharmacokinetics Pregabalin is a substrate of the L-amino acid carrier protein in the CNS. It does not display dose-dependent bioavailability. Food decreases the rate of absorption but not the bioavailability of the drug.[115]

Pregabalin is eliminated primarily by renal excretion as an unchanged drug, and therefore dosage adjustment is required in patients with significantly impaired renal function. In anuric patients, 50% of the dose is removed by 4 hours of hemodialysis.[115]

Adverse Effects Dizziness, somnolence, ataxia, blurred vision, and weight gain are the most frequently reported side effects. It is unknown if pregabalin causes aggressive behavior in children. A withdrawal reaction characterized by anxiety, nervousness, and irritability has been noted in patients being treated for generalized anxiety upon abrupt discontinuation of the drug.[116]

Drug Interactions Because pregabalin is predominantly excreted unchanged in the urine and undergoes negligible metabolism, drug interactions are unlikely.

Dosing and Administration Starting doses of pregabalin are divided into twice or thrice daily intervals. The manufacturer recommends that patients with end-stage renal disease maintained on hemodialysis receive a 25 to 75 mg daily dose with 25 to 75 mg given after every 4 hours of hemodialysis.

Advantages Pregabalin is somewhat more potent than gabapentin without the dose-limited GI absorption properties. It has minimal CNS side effects and no drug interactions.

Disadvantages It is a controlled substance class V. Like gabapentin it can cause weight gain and peripheral edema, especially as the dose is increased. There is no parenteral formulation available.

Place in Therapy Pregabalin is a second-line agent for patients with partial seizures who have failed initial treatment. It is also useful for chronic neuropathic pain and generalized anxiety disorder.[116]

Rufinamide

Pharmacology and Mechanism of Action Rufinamide is a triazole derivative structurally unlike any other AED. It suppresses neuronal hyperexcitability through prolongation of the inactivation phase of voltage-gated sodium channels.[117]

Pharmacokinetics Oral absorption is relatively slow with a t_{max} of 4 to 6 hours. At low doses (600 mg), the drug is relatively well absorbed (85%) when taken with food; however, the percentage of drug absorbed decreases with higher doses. Twice-daily dosing is recommended due to the slow absorption properties and the drug's short half-life (6–10 hours).[34] It is extensively metabolized with no active metabolites, with primary biotransformation by carboxylesterases. Although clinical data indicate that children and adults have similar pharmacokinetics, population pharmacokinetic modeling suggests that in the absence of interacting co-medication the drug may have a higher clearance in children.[117]

Adverse Effects The most common adverse effects include headache, dizziness, fatigue, somnolence, and nausea. These effects are dose dependent. Rufinamide may increase the incidence of convulsions in some patients, and may precipitate SE. Multiorgan hypersensitivity has occurred within 4 weeks of starting treatment in patients younger than 12 years of age.

Drug Interactions Rufinamide is a weak inhibitor of CYP2E1 and a weak inducer of CYP3A4; the later effect may be responsible for modestly lower levels of carbamazepine and triazolam when given concomitantly with rufinamide.[37] It may decrease the area under the curve of combination OCs containing ethinyl estradiol and norethindrone; however, it is not known if this is due to induction of CYP3A4 or uridine disphosphate glucuronosyl transferase (UDP-GT), or both. Rufinamide is responsible for a modest increase in the clearance of lamotrigine, phenobarbital, and phenytoin, and the effect is greater in children than adults. Carbamazepine, phenytoin, primidone, and phenobarbital significantly increase the clearance of rufinamide; however, it is believed this interaction is not entirely due to CYP450 enzyme induction. Valproic acid significantly decreases the clearance of rufinamide and elevates serum levels of rufinamide by 70%.

Dosing and Administration The initial dose of rufinamide is 400 to 800 mg/day given in divided doses with an increase in dose every other day until a maximum dose of 45 mg/kg/day or 3,200 mg/day (which ever is less) is obtained.

Advantages The drug is effective for seizures associated with Lennox—Gastaut syndrome without causing cognitive and psychiatric adverse effects. The dose can be rapidly escalated.

Disadvantages Drug interactions are common with rufinamide, and patients with Lennox—Gastaut are usually on multiple medications. It displays decreased absorption at higher doses and when taken on an empty stomach. The drug has caused convulsions and SE in some patients.

Place in Therapy As an adjunctive agent in controlling seizures in Lennox—Gastaut syndrome after patients have failed valproic acid, topiramate, and lamotrigine.

Tiagabine

Pharmacology and Mechanism of Action Tiagabine is a potent and specific inhibitor of GABA uptake into neuronal elements, thus, enhancing the action of GABA by decreasing its removal from the synaptic space.[118]

Pharmacokinetics Tiagabine is absorbed quickly and nearly completely after oral administration. There is a linear relationship between dose and serum concentrations. Children eliminate tiagabine slightly faster than adults. Hepatic impairment causes higher and more prolonged plasma concentrations of total and unbound drug. Renal dysfunction does not change its pharmacokinetics.[118] Tiagabine displays diurnal elimination, i.e., lower evening serum levels compared with morning levels.

Adverse Effects The most frequently reported adverse effects of tiagabine are dizziness, asthenia, nervousness, tremor, diarrhea, and depression. Adverse events usually are mild to moderate and transient, and most occur during dose titration.[119] CNS side effects can be diminished by taking tiagabine with food, thus slowing the absorption rate. It has increased the incidence of nonconvulsive SE in patients with chronic refractory partial epilepsy.[120] In addition, there are reports of SE or new onset seizures occurring in patients without a history of epilepsy.

Drug Interactions Food decreases the rate but not the extent of absorption. Tiagabine is displaced from protein by naproxen, salicylates, and valproate. However, tiagabine does not displace phenytoin, valproic acid, amitriptyline, tolbutamide, or warfarin.[118]

Dosing and Administration A clear dose-response has been demonstrated, and the minimal effective adult dose level is 30 mg/day. The initial dose is increased weekly.

Advantages Tiagabine has a known mechanism of action. It is the first drug marketed in the United States that acts only on GABA reuptake. It has linear pharmacokinetics and is not reported to interact with other drugs.

Disadvantages Initially high and rapid dosage escalation is associated with increased CNS side effects. Therefore, the drug must be started at a low dose and titrated gradually to response. Lower doses may be needed in patients with liver disease. Tiagabine is metabolized by CYP450 3A4 enzymes, and other drugs may alter its clearance. There is no parenteral formulation.

Place in Therapy Tiagabine is second-line therapy for patients with partial seizures who have failed initial therapy. It does not appear to have a role in primary generalized seizure types.

Topiramate

Pharmacology and Mechanism of Action Topiramate is a sulfamate-substituted monosaccharide with multiple modes of action involving voltage-dependent sodium channels, GABA-receptor subunits, high-voltage calcium channels, and kainate/AMPA subunits.[69] It also inhibits carbonic anhydrase, which likely is not a major mechanism of action.[69]

Pharmacokinetics Although generally considered to have linear absorption and elimination pharmacokinetics, a greater than

proportional increase in both maximal peak concentration and area under the plasma concentration versus time curve has been observed and probably is explained by saturable binding to erythrocytes.[121] Approximately 50% of the dose is excreted renally unchanged; however, its metabolism is increased by approximately 50% when given with enzyme-inducing AEDs. Renal tubular reabsorption may be involved prominently in the renal handling of topiramate.[122]

Adverse Effects The main adverse events of topiramate are ataxia, impaired concentration, memory difficulties, attentional deficits, confusion, dizziness, fatigue, paresthesia, somnolence, and "thinking abnormally," which rarely has included psychosis. Most of these occurred during rapid titration and at higher doses.[123] Word-finding difficulties can be a problem with topiramate and can occur in a significant number of patients, especially patients with left posterior temporal lobe epilepsy or simple partial seizures.[124] Concomitant therapy with topiramate, valproic acid, or phenobarbital can cause cognitive dysfunction. Nephrolithiasis has occurred in 1.5% of patients receiving topiramate, which is 2 to 4 times the incidence in the general population. Patients should be encouraged to maintain adequate fluid intake in order to minimize this problem. Topiramate can cause metabolic acidosis at doses as low as 50 mg/day. Risk factors for this condition include renal disease, severe respiratory disorders, SE, diarrhea, surgery, and the ketogenic diet. Metabolic acidosis in part may explain the anorexia and weight loss seen with this drug.[75]

Drug Interactions Oral clearance of digoxin is slightly increased when topiramate is added. Topiramate coadministration can cause increased phenytoin serum concentrations in some patients. The variable response can be explained by the intersubject variability in the proportion of phenytoin clearance attributed to CYP2C19 metabolism and whether the patient is a homozygous or heterozygous carrier of the mutant allele responsible for the CYP2C9 and/or CYP2C19 "poor metabolizer" phenotype. Topiramate can modestly increase the oral clearance of valproic acid and increase formation of the 4-ene—valproic acid metabolite. However, the clinical significance of this interaction is unclear. Topiramate increases the clearance of ethinyl estradiol in a dose-dependant manner. Topiramate doses of less than 200 mg/day are unlikely to alter OC pharmacokinetics.[125]

Dosing and Administration Topiramate should be titrated slowly to avoid adverse events with dosage increments every 1 to 2 weeks. For patients on other AEDs, doses greater than 600 mg/day do not appear to lead to improved efficacy and can cause increased adverse effects; however, higher doses may prove beneficial to individual patients who tolerate them.[126]

Advantages Topiramate has multiple mechanisms of action and is a broad-spectrum AED. Elimination is primarily renal, but hepatic metabolism occurs, especially if given concomitantly with enzyme inducers. It has linear pharmacokinetics and few drug interactions.

Disadvantages With rapid dosage escalation, topiramate can compromise cognitive functioning, including impaired word finding and impair short-term memory. Therefore, initial doses should be low, and titration must be slow. Renal stones and weight loss have been associated with topiramate use. The dose should be decreased in patients with renal failure. There is no parenteral formulation.

Place in Therapy Topiramate is a first-line AED for partial seizures as an adjunct and/or monotherapy. It is also approved for the treatment of tonic-clonic seizures in primary generalized epilepsy.

Valproic Acid/Divalproex Sodium

Pharmacology and Mechanism of Action Alterations of the synthesis and degradation of GABA do not fully explain the antiseizure activity of valproic acid. Valproic acid may potentiate postsynaptic GABA responses, may have a direct membrane-stabilizing effect, and may affect potassium channels.[127]

Pharmacokinetics Valproic acid appears to be absorbed completely from available oral dosage forms when administered on an empty stomach.[127] However, the rate of absorption differs among preparations. Peak concentrations occur in 0.5 to 1 hour with the syrup, 1 to 3 hours with the capsule, and 2 to 6 hours with the enteric-coated tablet.[127] The extended-release formulation (Depakote-ER) is FDA approved for patients with migraine headache and epilepsy. The bioavailability of this formulation is approximately 15% less than that of enteric-coated divalproex sodium (Depakote).

Valproic acid is extensively bound to albumin, and this binding is saturable. Accordingly, the valproic acid free fraction will increase as the total serum concentration increases. Because of this saturable binding, measurement of unbound serum concentrations may be a better monitoring parameter than the total valproic acid serum concentration, especially at higher concentrations or in patients with hypoalbuminemia.[73]

The primary route of valproic acid metabolism is β-oxidation, although up to 40% of a dose may be excreted as the glucuronide. At least 10 metabolites of valproic acid have been identified. Some of these may have weak anticonvulsant activity, and at least one metabolite may be responsible for the hepatotoxicity reported. One of the lesser oxidative metabolites, 4-ene-VPA, causes hepatotoxicity in rats. The formation of this metabolite is increased when valproic acid is given with enzyme-inducing drugs.[127] Valproic acid displays diurnal elimination with lower evening serum levels occurring than morning levels. It crosses into the placenta and concentrations may be up to 5 times higher in cord serum blood than in the mother due to higher binding in the fetal compartment.[128]

Adverse Effects The most frequently reported side effects are gastrointestinal (up to 20%), including nausea, vomiting, anorexia, and weight gain. Pancreatitis is rare. GI complaints may be minimized, but not totally alleviated, with the enteric-coated formulation or by giving the drug with food. Alopecia and hair changes are temporary, and hair growth returns even with continued dosing. Weight gain can be significant for many patients and is associated with an increase in fasting insulin and leptin serum levels.[129] The increase in serum insulin is believed to be caused by the inhibition of metabolism of insulin by the liver.[130] This has led to the development of insulin resistance in obese male and female subjects.[127] Valproic acid causes minimal cognitive impairment.[127]

The most serious side effect reported with valproic acid is hepatotoxicity. Hyperammonemia is common (50%) but does not necessarily imply liver damage. Most liver failure deaths have occurred in patients who were younger than 2 years of age, had mental retardation, and received multiple AEDs. Hepatotoxicity occurred early in the course of therapy. Patients who complain of nausea, vomiting, lethargy, anorexia, and edema in the first 6 to 12 months of therapy should have liver function evaluated. Multiple AEDs can alter the metabolism of valproic acid, leading to increased formation of the potentially liver-toxic 4-ene-VPA. Valproic acid has been shown to alter carnitine metabolism, and it has been postulated that a deficiency of carnitine alters fatty acid oxidation that could lead to both liver toxicity and hyperammonemia.[131] However, valproic acid hepatotoxicity has occurred in a patient taking supplemental carnitine, and a prospective study demonstrated no effect on well-being when carnitine was added. Although carnitine can ameliorate hyperammonemia in part, it is expensive, and there are only limited data to support routine supplemental use in patients taking valproic acid.[132]

Thrombocytopenia and alterations in platelet aggregation occur in the patients receiving valproic acid, and these phenomena are related to serum concentration. These blood coagulopathies may occur more frequently in children than in adults.[133]

Drug Interactions Because it is highly protein bound, other highly protein-bound drugs (e.g., free fatty acids and aspirin) can displace valproic acid.

Valproic acid can inhibit specific CYP P450 isozymes, epoxide hydrolase, and UGT isozymes. The addition of valproic acid to phenobarbital results in a 30% to 50% decrease in phenobarbital clearance and significant toxicity if the dose of phenobarbital is not reduced. Data also suggest that combination OCs may increase the clearance of valproic acid and lower serum levels by 20%.[32] In addition, carbapenems, especially merepenem can lower valproic acid levels.[134]

Dosing and Administration Valproic acid in some patients may have a half-life long enough for once-daily dosing with enteric-coated divalproex, but more frequent dosing is the norm. Based on half-life data, twice-daily dosing is feasible with any valproic acid dosage form; however, children and patients taking enzyme inducers can require dosing 3 to 4 times daily.[73] The serum concentration—dose relationship is curvilinear (e.g., the concentration-dose ratio decreases with increasing dose) probably because of increasing free concentrations and a resulting increase in clearance.[73]

Valproic acid is available as a soft gelatin capsule, an enteric-coated tablet, a syrup, a "sprinkle capsule," an extended-release formulation designed for once-daily dosing, and an IV formulation for replacement of oral therapy or in situations where rapid loading is necessary.[127] This parenteral formulation must not be given intramuscularly because it can cause tissue necrosis. The sprinkle capsule, designed to be opened and mixed with food, has a slower rate of absorption, which results in fewer fluctuations in the peak-to-trough ratio. The syrup is absorbed more rapidly than any solid dosage form. The enteric-coated divalproex tablet is not sustained release. It must be metabolized in the gut to valproic acid. The enteric coating reduces GI distress. The enteric coating causes delayed absorption, although once the enteric coating dissolves, sodium divalproex has absorption, metabolism, and elimination rates similar to those of the gelatin capsule. If a patient is switched from Depakote to Depakote-ER, the dose should be increased by 14% to 20%. Depakote-ER may be given once daily.

Advantages Valproic acid is available in multiple dosage formulations. The IV formulation is especially well tolerated. It has a wide therapeutic index and is considered a broad-spectrum AED. It is also used in other neurologic or psychiatric disorders (e.g., migraine headache, bipolar disorder).

Disadvantages Some patients report significant weight gain with valproic acid, which may limit compliance. It has other side effects, such as alopecia, tremor, pancreatitis, PCOS, and thrombocytopenia. It has been associated with hepatic necrosis in young children. As an enzyme inhibitor, it is involved in multiple drug—drug interactions.

Place in Therapy Valproic acid is first-line therapy for primary generalized seizures, including myoclonic, atonic, and absence seizures. It can be used as both monotherapy and adjunctive therapy for partial seizures, and it can be very useful in patients with mixed seizure disorders.

Vigabatrin

Pharmacology and Mechanism of Action Vigabatrin is an amino acid that is a structural analog of GABA. It is a racemic mixture consisting of two enantiomers with only the S(+)-enantiomer active. Vigabatrin is a selective, irreversible inhibitor of GABA-transaminase, the enzyme that degrades GABA, thereby increasing GABA levels in the CNS.[135]

Pharmacokinetics Vigabatrin undergoes virtually no metabolism and is excreted unchanged in the urine.[32] It is rapidly absorbed from the GI tract, and food has no effect on its absorption. Serum vigabatrin levels are linearly related to dosage, but therapeutic levels are not related to duration of effect; duration of effect is directly related to regeneration of the enzyme which metabolizes GABA. Since vigabatrin undergoes virtually no metabolism and is excreted renally, dosage adjustment is necessary in renally impaired patients. Children have a higher vigabatrin clearance than adults and therefore require higher mg/kg doses.[32]

Adverse Effects Vigabatrin may aggravate seizures, particularly absence and myoclonic seizures in patients with generalized epilepsies. Patients with history of depression, psychosis, or behavioral disturbances may be at greater risk to develop psychiatric effects.[135] Vigabatrin causes progressive, irreversible, bilateral concentric visual field constriction in a high percentage of patients. It may also reduce visual acuity in a dose-related and life exposure—related manner. Vigabatrin is associated with weight gain and edema, peripheral neuropathy, somnolence, and fatigue.[35] In up to 11% of patients (up to age 3 years) treated with high doses of the drug for infantile spasms, magnetic resonance imaging (MRI) findings have been strongly suggestive of intramyelinic edema in select brain areas. These findings appear to be reversible, and their significance is unclear.[136]

Drug Interactions Vigabatrin induces CYP2C and therefore decreases phenytoin plasma levels by approximately 20%. One study noted at least a 10% increase in serum carbamazepine levels in the majority of patients started on adjunctive therapy with vigabatrin, which has not been supported in clinical trials.[35]

Dosing and Administration Vigabatrin's initial dose in adults for refractory complex partial seizures is 1,000 mg/day given in two divided doses with an increase by 500 mg/day weekly until 3,000 mg/day is reached. Initial dose in infants and children for infantile spasms is 50 mg/kg/day given in two divided doses with an increase by 25 to 50 mg/kg/day every 3 days to maximum dose of 150 mg/kg/day.

Advantages Vigabatrin has been widely studied and used in numerous countries throughout the world.

Disadvantages Adverse effects are sizeable and significant. It is available only through a restricted distribution program (SHARE program), which requires providers and patients to register. Vision should be checked at baseline and every 3 months for up to 3 to 6 months after drug discontinuation.

Place in Therapy Vigabatrin is a first-line agent for infantile spasms, particularly those with tuberous sclerosis as the etiology. It is a third-line adjunctive agent for refractory partial epilepsy.

Zonisamide

Pharmacology and Mechanism of Action Zonisamide, a synthetic 1,2-benzisoxazole derivative classified as a sulfonamide, is chemically different from other AEDs. It is a broad-spectrum AED believed to exert its antiepileptic effect by inhibition of slow sodium channels, by blockade of T-type $Ca2^{+}$ channels, and possibly by inhibition of glutamate release. It also has a weak carbonic anhydrase inhibitory effect.[137]

Pharmacokinetics Zonisamide is well absorbed and reaches a maximum concentration in 2 to 5 hours. It is metabolized by CYP3A4 and to a much lesser extent by CYP2C19 and CYP3A5. Approximately 30% is excreted unchanged in the urine. Zonisamide is distributed to most tissues, but the drug is concentrated in the red blood cells. It crosses the placenta. The concentration in breast milk is similar to that in the plasma.[137]

Adverse Effects The most common adverse effects of zonisamide include somnolence, dizziness, anorexia, headache, nausea, agitation, word-finding difficulties, and irritability. Adverse

effects may be more common during rapid dose escalation. Because it is structurally related to sulfonamides, hypersensitivity reactions can occur (0.02% of patients), and zonisamide should be used with caution (if at all) in patients with a confirmed allergy to sulfonamide compounds. A 2.6% incidence of symptomatic kidney stones has been reported in patients treated in the United States.[138] Because of reports of modest, reversible declines in renal function in some patients, monitoring of renal function may be advisable for certain patients. Oligohidrosis has been reported. In addition, modest weight loss has been reported with this agent.[24,25,75]

Drug Interactions Zonisamide does not inhibit or induce the cytochrome P450 system.

Dosing and Administration Zonisamide is given once or twice daily, however, once-daily dosing causes greater fluctuations in serum concentrations and perhaps more side effects. The dose should be increased every 2 weeks to response. Zonisamide is stable for 48 hours when mixed with water, apple juice, or pudding.

Advantages Zonisamide has multiple mechanisms of action and may be a broad-spectrum AED. There is broad international experience with this drug. It has a very long half-life, which is suitable for once- or twice-daily dosing. Patients may experience modest weight loss.

Disadvantages The dos of zonisamide should be titrated slowly to patient response. Renal stones and oligohidrosis have been reported. In addition, cognitive impairment can occur, especially if the dosage is escalated rapidly. It should be avoided in patients allergic to "sulfa drugs."

Place in Therapy Zonisamide is approved for the adjunctive treatment of partial seizures. Zonisamide is potentially effective in a variety of partial and primary generalized seizure types.

PHARMACOECONOMIC CONSIDERATIONS

CLINICAL CONTROVERSY

The place in therapy of the newer drugs is still being determined. The cost of the newer AEDs generally is much higher that that of the older drugs. Given that, in general, the efficacy of the newer drugs is comparable with that of the older agents, many clinicians (and patients) have been slow to adopt this newer generation of drugs. It is important to recognize that overall effectiveness encompasses both efficacy and tolerability assessments. Generally speaking, the newer generation of AEDs possess fewer adverse effects and seems to be better tolerated than older, far less expensive agents such as the barbiturates. Some may also have less costly long-term adverse effects such as effects on bone metabolism or the fetus, and they may cause fewer drug interactions, which require higher doses of drugs to avoid treatment failures. These differences may well justify the difference in cost, however, this needs to be determined on an individual basis.

The direct costs of epilepsy include the cost of the drug, treatment of adverse events, emergency room visits, drug levels, laboratory tests, physician visits, rehabilitation, and transportation. Indirect costs include the costs associated with time lost from work, the inability to get a job, decreased productivity, and mortality.

It is difficult to assess the cost of epilepsy to society. Pashko and coworkers, using a cohort of Pennsylvania Medicaid patients, estimated that the total direct cost of epilepsy is in excess of $10 billion annually, with the majority of the per-patient costs incurred for inpatient hospitalization (uncontrolled seizures or treatment-related toxicity).[139] Another study suggested that the direct costs of epilepsy made up approximately 37% of the total costs, with indirect costs accounting for the remainder.[140] This study also indicated that the costs were much less for a patient who is well controlled than for a patient who is poorly controlled. Drug costs in the Pashko study accounted for approximately 10% of the total costs of epilepsy. In a large retrospective trial involving Medicaid patients in Florida, New Jersey, and Iowa, it was determined that nonadherence in taking AEDs was associated with a significantly higher incidence of hospitalization and visits to the emergency room, which translated to a sizable increase in overall costs.[141] Providing the best QOL possible is a treatment goal for patients with epilepsy, while maintaining a balance between side effects and the number of seizures.[142] QOL takes into account all the concerns of patients with epilepsy, including their social and economic concerns. This can best be assessed by the patient. Complete seizure freedom leads to the best QOL. In one study, driving was listed as the most important concern by 28% of patients, followed by employment (21%), independence (9%), safety (6%), AED side effects (5%), seizure unpredictability (5%), and seizure avoidance (5%).[143] Assessment of QOL as a therapeutic outcome ultimately may be more meaningful than measuring blood levels of the AEDs. It is clear that the cheapest drug in epilepsy (e.g., phenobarbital) is not the best because of the number of side effects. Drug therapy that controls seizures, decreases side effects, improves the QOL, and reduces the use of other healthcare resources would be cost-effective. Because epilepsy treatment continues to be highly individualized, the drug or combination of drugs that controls seizures with the least number of side effects will be the drug of choice for that patient no matter how expensive the drug acquisition cost.

Because many patients with epilepsy require minimal variation in blood concentrations to prevent seizures and avoid side effects, generic prescribing for epilepsy remains controversial. Issues related to generic use have been clearly delineated in the literature.[144,145] A strong argument for the use of generic AEDs is that they will save huge amounts of money and should not cause harm, if patients are selected wisely, e.g., those who are newly diagnosed, or who are not fully controlled, or who are not seizure free on brand product. There is only one randomized study comparing brand name and generic drug products which involved Depakene versus generic valproic acid. This study found no difference between the products. However, substantial data continue to accumulate from large, retrospective, observational studies which indicate that generics may increase health care costs from emergency room visits and hospitalizations. In addition, utilization of multiple generics in the same patient may create problems. A recent retrospective trial studied patients being treated with multiple topiramate generics and reported an increase in hospitalizations and injuries, again supporting increased health care costs with use of generics.[146] What has yet to be determined is whether bioequivalence translates into therapeutic equivalence in the use of generic AEDs and whether there is a subset of patients where this is not true.

EVALUATION OF THERAPEUTIC OUTCOMES

A therapeutic range should be established for each patient to define concentrations that result in minimal side effects and optimal seizure control. This therapeutic plasma concentration range should

be used to identify the appropriate patient-specific dose. Patients should be monitored long term for seizure control, comorbid conditions, social adjustment (including QOL assessments), drug interactions, compliance, and adverse effects. Periodic screening for comorbid neuropsychiatric disorders such as depression and anxiety is also important. Clinical response is more important than the serum drug concentrations.

Outcomes can be assessed by regular clinical monitoring, drug utilization review, and QOL assessments. Clinical monitoring involves identifying the number and type of seizures. Patients should record the severity and the frequency of seizures in a seizure diary. There should be a decrease in the number and/or severity of seizures. Patients and family should be questioned regularly to determine whether they are truly seizure free.

The treatment of epilepsy begins with a careful identification of the seizure type and selection of the most appropriate AED. Therapy should be initiated slowly, except in life-threatening situations, to avoid acute toxicity. Although most patients can be managed successfully on monotherapy, some patients' seizures remain uncontrolled despite the use of multiple AEDs. Some patients may be genetically refractory to AED therapy. The newer AEDs, as adjunctive therapy or monotherapy, offer additional opportunity to achieve complete seizure control. There is a continuing need for new AEDs and additional research in this area.

CHAPTER 66

Status Epilepticus

STEPHANIE J. PHELPS, COLLIN A. HOVINGA, AND JAMES W. WHELESS

KEY CONCEPTS

1. Status epilepticus (SE) is a neurologic emergency that is associated with significant morbidity and mortality.
2. Generalized convulsive status epilepticus (GCSE) is defined as any recurrent or continuous seizure activity lasting longer than 30 minutes in which the patient does not regain baseline mental status. Any seizure that does not stop within 5 minutes should be treated as impending SE.
3. There are two types of status epilepticus, GCSE and nonconvulsive status epilepticus (NCSE). GCSE is the most common type.
4. Most GCSE develops in patients with no history of epilepsy; however, a patient with preexisting epilepsy may experience GCSE as a result of acute anticonvulsant withdrawal, metabolic disorder, concurrent illness, or progression of neurologic disease.
5. Although the pathophysiology of GCSE is unknown, experimental models have shown that there is a dramatic decrease in γ-aminobutyric acid–mediated inhibitory synaptic transmission and that glutamatergic excitatory synaptic transmission sustains the seizures.
6. General treatment includes patient stabilization, adequate oxygenation, preservation of cardiorespiratory function, management of systemic complications, and aggressive assessment of underlying causes.
7. The main purpose of treatment is to prevent or decrease morbidity and mortality of prolonged seizures. Pharmacologic treatment needs to be rapid and aimed at terminating both electrical and clinical seizures. The probability of poorer outcomes increases with increased length of electrographic seizure activity.
8. Lorazepam is the preferred benzodiazepine in treatment of GCSE because of its long duration of action in the CNS.
9. Currently, the hydantoins (phenytoin and fosphenytoin) are the long-acting anticonvulsants used most frequently. Either phenytoin or fosphenytoin should be given concurrently with benzodiazepines.
10. The maximum rate of infusion for phenytoin and fosphenytoin in adults is 50 mg/min and 150 mg PE/min, respectively.
11. If GCSE is not controlled by two first-line agents (benzodiazepine plus hydantoin or phenobarbital), the GCSE is considered to be refractory. In these cases, newer anticonvulsants and/or pharmacologically induced coma should be used.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Status epilepticus (SE) is a common neurologic emergency that is associated with brain damage and death. 2 The traditional definition, provided by the International League Against Epilepsy Classification of Epileptic Seizures, defines SE as (1) any seizure lasting longer than 30 minutes whether or not consciousness is impaired or (2) recurrent seizures without an intervening period of consciousness between seizures.[1] Clinically, this definition has limited use, particularly in the case of generalized convulsive status epilepticus (GCSE), as the average seizure is less than 2 minutes; and only 40% of seizures lasting 10 to 29 minutes cease without treatment.[2,3] Pharmacoresistance[4] and mortality[3] significantly increase with increased seizure duration. Therefore, aggressive treatment of seizures lasting 5 minutes or more is strongly recommended. 3 SE can present in several forms (Table 66–1), including GCSE and nonconvulsive status epilepticus (NCSE).[1]

NCSE occurs in approximately 25% of those with SE and is characterized by a fluctuating or continuous "twilight" state that produces altered consciousness and/or behavior (e.g., lethargy, decreased mental function). An altered electroencephalogram (EEG) is the most important diagnostic and management tool.[5] In most instances, a benzodiazepine and/or valproate remain drugs of choice for NCSE.[5] Although intravenous (IV) hydantoin or phenobarbital can be tried in patients who fail to respond, general anesthesia or barbiturate coma is not appropriate.[5] The reader is referred to a recent review for a more comprehensive discussion of NCSE and its pharmacologic management.[5]

GCSE is the most common and severe form of SE and is characterized by repeated primary or secondary generalized seizures that involve both hemispheres of the brain and are associated with a persistent postictal state.[4] This chapter will focus on the epidemiology, pathophysiology, presentation, and management of GCSE.

EPIDEMIOLOGY

It is difficult to determine the true incidence of GCSE. The worldwide and United States incidence is thought to range between 1.2 to 5 million and 100,000 to 152,000 cases each year, respectively.[4] GCSE has no predilection for gender or socioeconomic status but does occur more frequently in nonwhites across all ages.[6] Most episodes of GCSE occur in individuals with no history of epilepsy;

TABLE 66-1 International Classification of Status Epilepticus

Convulsive		Nonconvulsive	
International	***Traditional Terminology***	***International***	***Traditional Terminology***
Primary generalized SE • Tonic-clonic[a,b] • Tonic[c] • Clonic[c] • Myoclonic[b] • Erratic[d]	Grand mal, epilepticus convulsivus	Absence[c]	Petit mal, spike-and-wave stupor, spike-and-slow-wave or 3/s spike-and-wave, epileptic fugue, epilepsia minora continua, epileptic twilight, minor SE
Secondary generalized SE[a,b] • Tonic • Partial seizures with secondary generalization		Partial SE[a,b] Simple partial Somatomotor Dysphasic Other types Complex partial	Focal motor, focal sensory, epilepsia partialis continua, adversive SE Elementary Temporal lobe, psychomopartial tor, epileptic fugue state, prolonged epileptic stupor, prolonged epileptic confusional state, continuous epileptic twilight state

SE, status epilepticus.
[a]Most common in older children.
[b]Most common in adolescents and adults.
[c]Most common in infants and young children.
[d]Most common in neonates.

TABLE 66-2 Etiology and Mortality for Pediatric and Adult Cases of Status Epilepticus

Etiology	Number of Cases (% Mortality) *n* = 200 Cases of Pediatric SE	Number of Cases (% Mortality) *n* = 512 Cases of Adult SE
Type I (no structural lesion)		
Infection	55 (5)	6 (35)
CNS infection	11 (0)	2 (20)
Metabolic	20 (5)	12 (36)
Low AED levels	16 (0)	24 (7)
Alcohol	0 (0)	13 (8)
Idiopathic	6 (0)	13 (18)
Type II (structural lesion)		
Anoxia/hypoxia	27 (13)	14 (65)
CNS tumor	3 (50)	5 (22)
CVA	5 (0)	26 (27)
Drug overdose	5 (0)	3 (23)
Hemorrhage	5 (11)	4 (35)
Trauma	13 (0)	3 (23)
Remote causes[a]	33 (5)	7 (13)

AED, antiepileptic drug; CVA, cerebrovascular accident; SE, status epilepticus.
Percentages do not add up to 100% because some patients had multiple etiologies.
[a]More than half of remote causes were congenital malformations and CVA in pediatric and adult patients, respectively.
Data from DeLorenzo et al.[6,8]

however, approximately 5% of adults and 10% to 25% of children with epilepsy will develop GCSE.[7] The incidence of GCSE is highest in those younger than 1 year of age and in those older than 60 years of age.

ETIOLOGY

Precipitating events for GCSE vary among studies and generally reflect different populations and referral patterns. 4 Most episodes that occur in known epileptics occur because of acute anticonvulsant withdrawal, a metabolic disorder or concurrent illness, or progression of a preexisting neurologic disease. Common etiologies and mortality rates are shown in Table 66–2.[6,8] Precipitating events for GCSE are divided into those with and without neurologic structural lesions or those with a precipitating injury or insult. Cases with structural lesions or those with a specific neurologic insult are associated with a poor prognosis.

There are major differences in etiologies for pediatric and adult patients (see Table 66–2). During their first few weeks of life, infants who are born to addicted mothers can develop drug withdrawal seizures. Other neonates can develop GCSE because of a pyridoxine deficiency, which should resolve within hours following IV pyridoxine (100 mg). Acute encephalopathy and metabolic disorders are the major causes of GCSE in patients younger than 1 year of age. In young children, the cause is frequently a nonspecific illness such as fever and/or a viral illness. The most frequent precipitating events in adults are cerebrovascular disease, anticonvulsant withdrawal, and low anticonvulsant serum concentrations. Cerebrovascular disease is the leading cause in those who have their first seizures after age 60. A number of prescription, over-the-counter, and recreational drugs should be considered in anyone with new-onset GCSE. Elevated anticonvulsant serum concentration or rapid anticonvulsant withdrawal can also precipitate GCSE.

MORBIDITY AND MORTALITY

GCSE is harmful to the brain and is associated with morbidity. However, whether the morbidity results from the underlying etiology or the GCSE itself remains to be determined. Most contend that the GCSE is responsible for the morbidity. Neuronal damage in animal models is evident following 30 to 60 minutes of GCSE regardless of the inducing stimulus, and most animals progress to develop epilepsy following a prolonged seizure. Interestingly, inhibiting the neuronal damage associated with seizures does not prevent the development of epilepsy, suggesting that the seizures themselves may be harmful. It is hard to establish a relationship between GCSE and long-term outcomes because it is difficult to weigh the effects of seizure type, etiology, duration, concurrent physiologic events, and therapy or lack thereof. It has been shown that patients with a history of prolonged febrile seizures who later developed epilepsy share similar histopathologic changes (i.e., hippocampal sclerosis) to those found in animal models of GCSE.[9,10] In these cases the period between the initial GCSE and the first epileptic seizure may be months to decades, suggesting a possible link between GCSE and the development of epilepsy. Importantly, studies of GCSE show that the currently available anticonvulsants do not reproducibly prevent the development of epilepsy following prolonged seizures.[9,11]

Patients who develop epilepsy following prolonged GCSE are less likely to experience remission of their seizures and may have decreased cognitive and memory function, mental retardation, or neurologic deficits.[4] Most studies have found that younger children, the elderly, and those with preexisting epilepsy have a higher propensity for sequelae. Unless accompanied by an underlying neurologic abnormality, fever-induced GCSE is less likely to be associated with sequelae.

The estimated mortality rate in the United States following GCSE ranges between 22,000 and 42,000 individuals per year.[8] Recent

estimates suggest a mortality rate of up to 16% in children,[12] 20% in adults,[4] and 38% in the elderly.[6] When compared with other populations, neonates have a higher mortality and more neurologic sequelae.

Table 66–2 summarizes the etiology and corresponding mortality rates for GCSE.[6,8] Interestingly, the mortality associated with many etiologies is significantly greater in adults than in children. Unresponsive patients may die from GCSE, but more frequently they die from the acute illness that precipitated the GCSE. For example, patients with serious central nervous system (CNS) structural changes (e.g., hemorrhage, stroke) have a poor prognosis, whereas those (i.e., 80%–90%) with no structural lesion generally respond to IV phenytoin.

Two variables that affect outcome are the time between onset of GCSE and the initiation of treatment and the duration of the seizure. Mortality significantly increases with increased seizure duration (e.g., 2.6% for those with seizures 10–29 minutes vs 19% for those with seizures lasting >30 minutes).[2] Patients with GCSE lasting longer than 60 minutes have a higher mortality rate (32%) than those with seizures lasting less than 60 minutes (2.5%).[8] Mortality has decreased over the past decade and probably reflects a recognition of the need to initiate sequenced therapy immediately, and a greater understanding of the pathogenesis of GCSE.

PATHOGENESIS

Seizures occur when the excitatory neurotransmission overcomes inhibitory impulses in one or more brain regions (i.e., neural networks). Most seizures are brief (less than 5 minutes), largely because the brain's inhibitory mechanisms restore the balance of normal neurotransmission.[4] It is unknown why the mechanisms that control normal brain homeostasis fail. However, when seizures occur in close succession or the magnitude of the proconvulsant stimulus is severe, compensatory mechanisms can be overwhelmed and lead to GCSE.

5 Although the exact cellular mechanisms responsible for the production of abnormal neural impulses are unknown, it appears that seizure initiation is caused by an imbalance between excitatory (e.g., glutamate, calcium, sodium, substance P, and neurokinin B) and inhibitory neurotransmission (e.g., γ-aminobutyric acid [GABA], adenosine, potassium, neuropeptide Y, opioid peptides, and galanin).[13] Seizure maintenance associated with GCSE is largely caused by glutamate acting on postsynaptic *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-isoxazole-4-propionate (AMPA)/kainate receptors. Most of what is known about GCSE has focused on gated ion channels, with less known about receptor—second messenger systems (e.g., metabotropic glutamate receptors).[13]

During GCSE, glutamate activation of the NMDA and AMPA receptors causes opening of the gated calcium and sodium channels, which lead to neuronal depolarization. Sustained depolarization may maintain GCSE and eventually cause neuronal death through calcium-, free radical-, and kinase-mediated events.[9] Although drugs acting as NMDA and AMPA receptor antagonists seem attractive, it is likely that glutamate is not the sole mechanism for GCSE and that other mechanisms become increasingly important as the duration of seizures increases.

$GABA_A$ postsynaptic receptors control chloride channels to produce hyperpolarization (inhibition) of the postsynaptic cell membrane. These receptors have binding sites for GABA and select anticonvulsants (e.g., phenobarbital and benzodiazepines) and enhance $GABA_A$-mediated chloride inhibitory currents. It was previously thought that a decrease in presynaptic GABA led to prolonged seizures; however, it is currently held that GABA concentrations increase during the early phases of GCSE and continue to be elevated during late GCSE. Prolonged seizures lead to decreased inhibitory $GABA_A$-receptor density because of postsynaptic receptor endocytosis. Additionally, modification of $GABA_A$ receptors during SE may decrease response to both endogenous GABA and GABA agonists.[10] Clinically, the relative potencies of benzodiazepines and phenobarbital can be reduced up to tenfold if seizures persist for more than 30 minutes.[10] A similar phenomenon occurs with sodium channel antagonists (phenytoin); however, the magnitude of resistance is believed to be less.

PATHOPHYSIOLOGY

As GCSE continues, there are systemic alterations, progression of motor phenomena, and development of specific EEG findings.[14] Two distinct and predictable phases have been identified. Phase I occurs during the first 30 minutes of seizure activity, and phase II immediately follows. Although these systemic complications affect the prognosis of GCSE, a prolonged seizure can destroy neurons independent of these systemic events.[9] In fact, the systemic effects of induced seizures in animals can be blocked, but the damage to the neocortex, cerebellum, and hippocampus persists.

During phase I, each seizure produces marked increases in plasma epinephrine, norepinephrine, and steroid concentrations that can cause hypertension, tachycardia, and cardiac arrhythmias.[15] Within minutes, arterial systolic pressures can rise to above 200 mm Hg, and heart rate can increase by 83 beats per minute. Although blood pressure returns to normal within 60 minutes, mean arterial pressure does not fall below 60 mm Hg; hence, cerebral perfusion pressure is not compromised. In animals, cerebral blood flow is also increased, thereby protecting neurons from hypoxic injury.

Seizure-induced increases in sympathetic and parasympathetic stimulation of the heart, in the presence of a hypoxic myocardium, can result in ventricular arrhythmias. Autonomic neuron stimulation can cause a release of insulin and glucagon. Concurrently, circulating catecholamines cause an elevation of hepatic cyclic adenosine monophosphate, producing glycogenolysis. Although the patient can be hyperglycemic initially, serum glucose concentration begins to fall.

Seizure-induced muscular contractions and hypoxia cause lactic acid release, which can produce a severe acidosis that can be accompanied by hypotension and shock. Muscle contractions can be so severe that rhabdomyolysis with secondary hyperkalemia and acute tubular necrosis can occur. The airway can be obstructed, causing the patient to become cyanotic or hypoxic. Additionally, an increase in salivation and tracheal and pulmonary secretions can cause aspiration pneumonia. Although transient pleocytosis can develop, it should not be attributed to SE until infectious causes have been eliminated.

Between seizures, the EEG slows, and blood pressure normalizes. Although metabolic demands are increased, the brain is able to adequately compensate. During phase II (e.g., seizures exceed 30 minutes), the EEG ictal discharge and clonic motor activity become continuous, and the patient begins to decompensate. Despite elevated levels of catecholamines, the patient can become hypotensive. During this time, autoregulation of cerebral blood flow becomes dependent on mean arterial pressure and begins to fail. There continues to be an excessive consumption of oxygen and glucose; however, compensatory mechanisms are no longer able to keep up with demands.

During this time, the serum glucose concentration may be normal or decreased. Profound hypoglycemia, secondary to hyperinsulinemia, can occur in those with hepatic dysfunction or reduced glycogen stores. Hyperthermia and respiratory deterioration with hypoxia and ventilatory failure can develop. Metabolic and

biochemical complications, including respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and azotemia may develop. There is increased sweating and salivation.

CLINICAL PRESENTATION OF GCSE

Symptoms

- Impaired consciousness (e.g., lethargy to coma)
- Disorientation once GCSE is controlled
- Pain associated with injuries (e.g., tongue lacerations, shoulder dislocations, head trauma)

Early Signs

- Generalized convulsions
- Acute injuries or CNS insults that cause extensor or flexor posturing
- Hypothermia or fever suggestive of intercurrent illnesses (e.g., sepsis or meningitis)
- Incontinence
- Normal blood pressure or hypotension and respiratory compromise

Late Signs

- Clinical seizures may or may not be apparent
- Pulmonary edema with respiratory failure
- Cardiac failure (dysrhythmias, arrest, cardiogenic shock)
- Hypotension or hypertension
- Disseminated intravascular coagulation, multisystem organ failure
- Rhabdomyolysis
- Hyperpyremia

Initial Laboratory Tests

- Complete blood count (CBC) with differential
- Serum chemistry profile (e.g., electrolytes, calcium, magnesium, glucose, serum creatinine, alanine aminotransferase [ALT], aspartate aminotransferase [AST])
- Urine drug/alcohol screen
- Blood cultures
- Arterial blood gas to assess for metabolic and respiratory acidosis
- Serum drug concentration if previous anticonvulsant suspected or known

Other Diagnostic Tests

- Spinal tap if CNS infection suspected
- EEG should be obtained on presentation and once clinical seizures are controlled
- CT with and without contrast
- MRI
- Radiograph if indicated to diagnose fractures

CLINICAL PRESENTATION AND DIAGNOSIS

Accurate diagnosis requires observation, physical examination, laboratory assessment, EEG, and neurologic imaging. The nature and duration of the seizure should be obtained, and a diagnosis of GCSE should not be made until a clinician has observed at least one seizure. Most patients have an altered consciousness that ranges from obtunded to marked lethargy and somnolence with pronounced eyes-open unresponsiveness and waxy rigidity. Motor features can include muscle contractions, extensor or flexor posturing, and spasms. Over time, the clinical manifestations become less apparent. This has important ramifications in that seizures appear to have terminated without treatment or when an ineffective therapy is given.

In addition to an assessment of language and cognitive abilities, the physical and neurological examinations should assess motor, sensory, and reflex abnormalities, pupillary response, asymmetry, and posturing. The patient should also be examined for secondary injuries (e.g., tongue lacerations, shoulder dislocations, and head and facial trauma).

Laboratory tests are essential to the diagnosis of various etiologies. Hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hypocalcemia, and renal failure all can cause seizures. A urine drug screen can help eliminate the possibility of illicit drug use or drug overdose. Serum drug concentration(s) should be obtained in those on chronic anticonvulsants, because high concentrations of certain medications can induce seizures, and low concentrations can reflect noncompliance or rapid drug withdrawal. A baseline serum concentration is necessary to determine whether a loading dose of a specific anticonvulsant is required. Assessment of other laboratory parameters (e.g., albumin, renal function, and hepatic function) that affect anticonvulsant dosing also can be useful. An EEG is a valuable diagnostic tool, particularly in those with prolonged GCSE in whom clinically apparent seizures are not always evident, but therapy should not be delayed while awaiting testing or results.

Once seizures have stopped, it is important to determine if the patient is febrile or has a systemic or CNS infection. Many physiologic consequences of GCSE (e.g., leukocytosis, pleocytosis, and hyperthermia) produce symptoms that can be confused with other conditions. If a CNS infection is suspected, empiric antibiotics should be started, and a spinal tap should be performed. Computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained to eliminate vascular, neoplastic, or infectious etiologies.

TREATMENT

Various treatments are available for the management of GCSE. These range from abortion of impending SE with rescue medications to the use of pharmacological and nonpharmacological therapies for GCSE and refractory/resistant SE.

DESIRED OUTCOMES

The short-term desired outcomes of treatment of GCSE are (1) immediate termination of all clinical and electrical seizure activity, (2) no clinically significant adverse effects, and (3) lack of recurrent seizure activity. [6] [7] The long-term desired outcomes are to minimize or avoid the likelihood of pharmacoresistent epilepsy and/or the development of neurologic sequelae that significantly impact quality of life.

NONPHARMACOLOGIC THERAPY

Vital signs should be assessed, an adequate and protected airway should be established, ventilation should be maintained, and oxygen should be administered. Frequent arterial blood gas determinations should assess for metabolic acidosis, which should be treated with sodium bicarbonate if the pH is less than 7.2. Assisted ventilation should be used to correct respiratory acidosis.

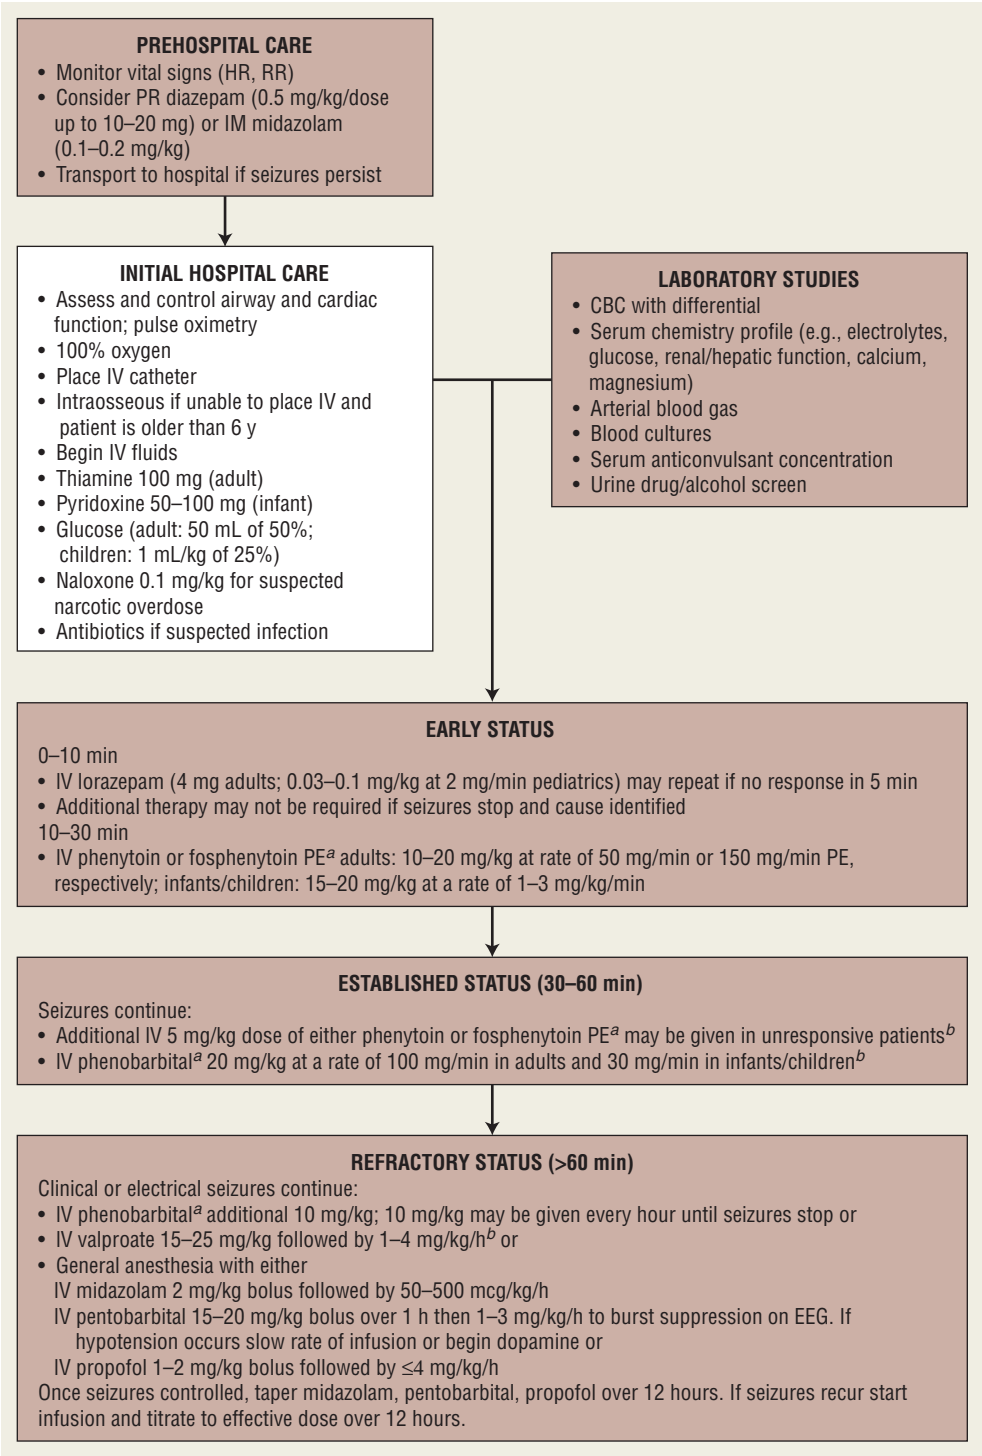

FIGURE 66-1. Algorithm for the treatment of GCSE. (CBC, complete blood count; EEG, electroencephalogram; GCSE, generalized convulsive status epilepticus; HR, heart rate; PR, per rectum; RR, respiratory rate.) [a]Because variability exists in dosing, monitor serum concentration. [b]If seizure is controlled, begin maintenance does and optimize using serum concentration monitoring.

Because electrical seizures may persist in the absence of clinical motor manifestations, an EEG should be performed in anyone who continues to have altered consciousness after clinical control of their seizures. Although hypoglycemia rarely causes GCSE, adults and children should receive 50 mL of a 50% dextrose solution, and 1 mL/kg of a 25% dextrose solution, respectively.[4,7] Because Wernicke encephalopathy can develop in alcoholics, adults should receive IV thiamine (100 mg) prior to glucose.[4] Serum glucose concentration should be determined to assess the need for further supplementation.

PHARMACOLOGIC THERAPY

When a seizure does not stop within 5 minutes, or when doubt exists regarding the diagnosis, patients should be treated as if they have GCSE. Figure 66–1 provides an algorithm for the treatment of GCSE.

TABLE 66-3 Medications Used in the Initial Treatment of GCSE

	Loading Dose (Maximum Dose)		Rate of Infusion		Maintenance Dose	
Anticonvulsant (Route)	***Adult***	***Pediatric***	***Adult***	***Pediatric***	***Adult***	***Pediatric***
Diazepam (IV bolus)	0.25 mg/kg[a,b,c] (40 mg)	0.25–0.5 mg/kg[a,c] (0.75 mg/kg)	<5 mg/min	<5 mg/min	Not used	Not used
Fosphenytoin IV	15–20 mg PE/kg	15–20 mg PE/kg	150 mg PE/min	3 mg PE/kg/min	4–5 mg PE/kg/d	5–10 mg PE/kg/d
Lorazepam (IV bolus)	4 mg[a,b,c] (8 mg)	0.1 mg/kg[a,c] (4 mg)	2 mg/min	2 mg/min	Not used	Not used
Midazolam IV	200 mcg/kg[a,d]	150 mcg/kg[a,d]	0.5–1 mg/min	2–3 min	50–500 mcg/kg/h[e]	60–120 mcg/kg/h[e]
Phenobarbital IV	10–20 mg/kg[e]	15–20 mg/kg[e]	100 mg/min	30 mg/min	1–4 mg/kg/d[e]	3–5 mg/kg/d[e]
Phenytoin IV	10–20 mg/kg[f]	10–20 mg/kg[f]	50 mg/min[g]	1–3 mg/kg/min	4–5 mg/kg/d[e]	5–10 mg/kg/d[e]

GCSE, generalized convulsive status epilepticus; PE, phenytoin equivalents.
[a]Doses can be repeated every 10 to 15 minutes until the maximum dosage is given.
[b]Initial doses in the elderly are 2 to 5 mg.
[c]Larger doses can be required if patients chronically on a benzodiazepine (e.g., clonazepam).
[d]Can be given by the intramuscular, rectal, or buccal routes.
[e]Titrate dose as needed.
[f]Administer additional loading dose based on serum concentration.
[g]The rate should not exceed 25 mg/min in elderly patients and those with known atherosclerotic cardiovascular disease.

7 There are four immediate goals in the management of GCSE: (1) patient stabilization, including adequate oxygenation, preservation of cardiorespiratory function, and management of systemic complications; (2) accurate diagnosis of the subtype of GCSE and identification of precipitating factors; (3) termination of clinical and electrical seizures as early as possible; and (4) prevention of seizure recurrence. The benzodiazepines, hydantoins, and barbiturates are the most commonly used classes of anticonvulsants for the initial treatment of GCSE.

Benzodiazepines

The benzodiazepines are effective initial therapy in most patients and should be administered as soon as possible. Generally, one or two IV doses will terminate seizures within 2 to 3 minutes.[4] All benzodiazepines are equally effective; therefore, the preferred agent is determined by differences in the pharmacokinetic, pharmacoeconomic, and adverse-effect profiles.

Diazepam is extremely lipophilic with a large volume of distribution (1–2 L/kg).[15] Although it initially distributes into the brain within seconds, it rapidly redistributes into fat, causing its CNS half-life to be less than 1 hour and its duration of effect to be less than 30 minutes.[15] The rapid decrease in brain concentration can cause seizure recurrence; hence, a longer-acting anticonvulsant (e.g., phenytoin or phenobarbital) should also be given. The initial dose of diazepam (Table 66–3) can be repeated if there is no response within 5 minutes.[15]

8 Most practitioners consider lorazepam the benzodiazepine of choice.[4,15] A recent Cochrane Database Review concluded that lorazepam is as effective and safer than diazepam in children.[16] It is less lipid soluble than diazepam and takes longer to achieve peak concentrations in the brain; however, its minimal redistribution into fat results in a longer duration of action in the CNS that can provide seizure protection for up to 24 hours.[4,15] It also has a higher-affinity binding to the benzodiazepine receptor than diazepam.

Initial lorazepam dosing (Table 66–3) can be repeated if the patient does not respond in 5 minutes.[4,15] Patients chronically on a benzodiazepine (e.g., clonazepam) might have developed tolerance and could require larger doses than other patients. Diazepam and lorazepam cause vein irritation and should be diluted with an equal volume of compatible diluent before administration. Diazepam and lorazepam contain propylene glycol, which can cause dysrhythmia and hypotension if administered too rapidly.[15] Because of slow and erratic absorption, they should not be given intramuscularly (IM).

CLINICAL CONTROVERSY

The positioning of midazolam among the medications used to treat GCSE is controversial. Some investigators recommend that midazolam should be the anticonvulsant of first choice and, therefore, should be used in lieu of lorazepam; others argue that it should be used after a hydantoin has failed; still others recommend it only for refractory GCSE.

Unfortunately, midazolam has an extremely short half-life and must be given by continuous infusion. Various routes of administration (e.g., buccal, IM, intranasal) have been used successfully to terminate seizures when IV access cannot be established. Because of its increased solubility, midazolam has a more reliable IM absorption than either diazepam or lorazepam. In fact, some practitioners have recommended that IM midazolam be given by emergency personnel as first-line treatment in the out-of-hospital setting.[17] Buccal administration is easily accomplished, the volume of fluid is small enough (e.g., 2–5 mL) that aspiration is unlikely. A recent Cochrane Database Review concluded that buccal midazolam is more effective than rectal diazepam in children.[16]

All benzodiazepines can impair consciousness and interfere with neurologic assessment. Although rare, brief (less than 1 minute) cardiorespiratory depression can necessitate assisted ventilation or require intubation. This is especially true if a benzodiazepine is used concomitantly with a barbiturate. Hypotension secondary to a reduction in vasomotor tone can occur following large doses.[4]

CLINICAL CONTROVERSY

The choice of long-acting anticonvulsant to give following the initial benzodiazepine is controversial. According to the Working Group on Status Epilepticus, phenytoin should be used in seizures that recur after treatment with a benzodiazepine.[15] Although this has been the practice for decades; no studies have documented the superiority of a hydantoin over other anticonvulsants. Thus, it is questionable if a hydantoin should be administered alone, in larger doses, or at all when seizures recur following benzodiazepine administration.

Phenytoin

9 A hydantoin is the second-line agent in GCSE that is unresponsive to the benzodiazepines or in seizures that recur after successful treatment with a benzodiazepine.[4] Although it is effective in terminating seizures in 40% to 91% of patients,[15] it can be inferior to lorazepam, phenobarbital, or diazepam plus phenytoin at stopping GCSE within 20 minutes of their infusion.[18,19]

Phenytoin has a long half-life (20–36 hours) and causes less respiratory depression and sedation than the benzodiazepines or phenobarbital;[15] however, it cannot be delivered rapidly enough to be considered a first-line single agent. Injectable phenytoin should be diluted to less than or equal to 5 mg/mL in normal saline. Microcrystals will precipitate if it is mixed in a glucose-containing solution. The vehicle (40% propylene glycol) can cause administration-related hypotension and cardiac arrhythmias. These effects are more likely to occur if large loading doses are given to elderly individuals with preexisting cardiac disease or in critically ill patients with marginal blood pressure.[15] Vital signs and an ECG should be obtained during administration. The infusion rate should be slowed if the QT interval widens or if hypotension or arrhythmias develop.[15] 10 The maximum rate of infusion is 50 mg/min in adults, 25 mg/min in the elderly, and 3 mg/kg/min in children weighing less than 50 kg (110 lb).[4]

Suggested IV loading doses are provided in Table 66–3.[15] A reduction in the loading dose is recommended for elderly patients,[15] and a larger loading dose is required in obese individuals.[20] If the patient has been on phenytoin prior to admission and the serum concentration is known, this should be considered in determining a loading dose. Although some advocate the administration of an additional 5 mg/kg in those with unresponsive GCSE, there is no evidence that this will be beneficial. This practice can cause concentrations to exceed the reference range and produce toxicity. Because phenytoin has poor lipid solubility and enters the brain slowly, it can take up to 60 minutes before the pharmacodynamic effect is apparent. This delay is important when considering administration of a second 5 mg/kg loading dose. Therapeutic serum concentrations, 10 to 20 mg/L (40–79 μmol/L), generally do not persist more than 24 hours; hence, maintenance doses (see Table 66–3) should be started within 12 to 24 hours of the loading dose.

Phenytoin has an alkaline pH, which may cause pain and burning during infusion; phlebitis can occur with chronic infusion, and tissue necrosis is likely on infiltration. IM administration is not recommended because absorption is delayed and erratic, and phenytoin can crystallize in tissue. Although oral loading doses have been used in patients not actively seizing, it may take 4 to 12 hours before adequate serum concentrations are obtained; thus, this practice is not recommended.

CLINICAL CONTROVERSY

The debate continues as to which hydantoin is preferred in GCSE. Although phenytoin has been used for decades, it is associated with a variety of problems related to its formulation. Conversely, fosphenytoin is associated with less infusion pain and IV-site complications and fewer hemodynamic effects than phenytoin. Although most practitioners believe that fosphenytoin is clearly a "better" formulation, many struggle with the advantages of fosphenytoin, given its cost.

Fosphenytoin

Fosphenytoin, a water-soluble phosphate ester, has no known pharmacologic activity.[21] It is converted rapidly (7–15 minutes) and completely (100%) to phenytoin by blood and tissue phosphatases after IV and IM dosing.[21] The conversion delay was a concern initially; however, this time is offset by high protein binding, saturable binding at high concentrations, and the rapid rate of infusion.[21] It does not contain propylene glycol and is compatible with most common IV fluids.

Nystagmus, dizziness, and ataxia are the most frequent adverse events and are attributed to phenytoin. The frequency of ECG or blood pressure changes is less than that for phenytoin. Nonallergic paresthesia and pruritus of the face and groin are unique to fosphenytoin and are related to dose and infusion rate, and rarely require discontinuation of fosphenytoin. These side effects typically subside within 5 to 10 minutes after the infusion.[21]

Fosphenytoin should be dosed using phenytoin equivalents (PE), thereby obviating the need for interconversion between phenytoin and fosphenytoin. The loading dose and rates of administration of fosphenytoin can be found in Table 66–3. Because of delays in achieving adequate phenytoin serum concentrations, a loading dose should not be given IM unless IV access is impossible. Continuous ECG, blood pressure, and respiratory status monitoring is recommended for all loading doses.

Fosphenytoin serum concentrations have no value. Serum phenytoin concentrations should be used for therapeutic drug monitoring, and the desired serum concentration range is the same as that for phenytoin. Fosphenytoin cross-reacts with some phenytoin immunoassays causing an overestimation of phenytoin concentration; hence, blood should not be obtained for at least 2 hours after IV and 4 hours after IM administration.[21]

CLINICAL CONTROVERSY

There are three different opinions regarding the use of phenobarbital in GCSE. Because barbiturates cause CNS and respiratory depression, as well as hypotension, most contend that phenobarbital should be the third-line agent when a benzodiazepine plus phenytoin has failed. Others suggest that the barbiturates are as safe and effective as other anticonvulsants and should be the drug of choice following a benzodiazepine. Still others support continuous-infusion midazolam as the third-line anticonvulsant before the barbiturates. Currently, most practitioners agree that phenobarbital is the long-acting anticonvulsant of choice in patients with hypersensitivity to the hydantoins or in those with cardiac conduction abnormalities.

Phenobarbital

Phenobarbital has biphasic distribution into body organs.[22] During phase I, the drug distributes into highly vascular organs, but it does not distribute into the brain. With the exception of fat, phenobarbital distributes throughout the body during phase II[22]; hence, lean body mass should be used in calculating doses in obese patients.[22] Although the highest brain concentrations occur 12 to 60 minutes after an IV dose,[22] seizures are controlled within minutes of the loading dose.[19] Despite two studies that found phenobarbital to be as effective as phenytoin, lorazepam, or diazepam plus phenytoin in patients with GCSE,[18] the Working Group on Status Epilepticus recommends that phenobarbital be given after a benzodiazepine plus phenytoin has failed.[15]

The loading and maintenance dose are given in Table 66–3. When necessary, larger loading doses (30 mg/kg) have been used in neonates without adverse effects. If the initial loading dose does not stop the seizures within 20 to 30 minutes, an additional 10 to 20 mg/kg can be given. If seizures continue, a third 10 mg/kg load can

be given.[23] Phenobarbital exhibits first-order linear pharmacokinetics, and there is no maximum dose beyond which further doses are likely to be ineffective.[23] Once GCSE is controlled, the maintenance dose should be started within 12 to 24 hours.

Although injectable phenobarbital contains propylene glycol, it can be given more rapidly than phenytoin (see Table 66–3). It can be given IM, but its rate of absorption is too slow to be effective. Phenobarbital can depress consciousness and respiration. The risk of apnea and hypopnea can be more profound in patients treated initially with benzodiazepines.[4,15] If significant hypotension develops, the infusion should be slowed or stopped.[15]

TREATMENT OF REFRACTORY GCSE

11 When adequate doses of a benzodiazepine, hydantoin, or barbiturate have failed, the condition is termed *refractory*. Approximately 10% to 15% of patients will develop refractory GCSE, and approximately 30% whose seizures are "clinically" controlled will have persistent electrical manifestations after administration of these anticonvulsants. When a patient develops refractory GCSE, an intense search should be performed for an acute or progressive cause.

It should be remembered that the longer GCSE lasts, the harder it is to treat and that failure to treat aggressively early in the course of disease increases the likelihood of nonresponse.[15] While the goal is to stop electrical epileptiform activity, there is no consensus regarding the anticonvulsant of choice, sequencing of therapy, or treatment of refractory GCSE. Approaches used include the continuous infusion of a benzodiazepines, medically induced coma, valproate, lacosamide, levetiracetam, topiramate, propofol, or lidocaine. Doses for these agents can be found in Table 66–4. A meta-analysis compared midazolam, propofol, and pentobarbital in refractory GCSE.[25] Overall response rates were significantly greater in those treated with pentobarbital (92%) compared to midazolam (80%) and propofol (73%). Breakthrough seizures were more commonly observed with midazolam (51%) versus propofol (15%) and pentobarbital (12%). Although pentobarbital had a greater response rate, clinically significant hypotension was more common. Mortality rates were similar for the three drugs.

Benzodiazepines

Some advocated that anesthetic doses of midazolam should be the first-line agent in refractory GCSE.[25] Table 66–4 contains the loading and maintenance doses of midazolam. Most patients respond to these doses within an hour, but the continuous-infusion rate should be increased every 15 minutes in those who do not. Because tachyphylaxis can develop, frequent increases in the infusion rate can be necessary, and dosing should be guided by EEG response.

Once GCSE is terminated, dosages can be decreased by 1 mcg/kg/min every 2 hours. Successful discontinuation is enhanced by maintaining the patient's phenytoin and phenobarbital serum concentration(s) above 20 mg/L (79 μmol/L) and 40 mg/L (172 μmol/L), respectively. Because of midazolam's short half-life, patients can return to consciousness more rapidly than those receiving larger doses of more sedating anticonvulsants (e.g., phenytoin, phenobarbital). Generally, continuous-infusion midazolam has been well tolerated, with few cases of hypotension and respiratory depression. Hypotension and poikilothermia can occur and can require supportive therapies.

Large-dose continuous-infusion lorazepam also has been used successfully.[26] Unlike midazolam, lorazepam contains propylene glycol, which can accumulate during continuous infusions. Propylene glycol toxicity can cause a marked osmolar gap, metabolic acidosis, and renal toxicity.[27]

Medically Induced Coma

If there is an inadequate response to large doses of midazolam, anesthetizing the patient to suppress the cerebral ictal discharge is recommended.[15,24] Although it is likely that the patient is already being mechanically ventilated, intubation and respiratory support are mandatory during barbiturate coma. Because hypotension is a concern, it is essential that vital signs be monitored continuously. A short-acting barbiturate (usually either pentobarbital or thiopental) generally is preferred because it allows a more rapid reversal of coma.

Several sources note that the initial loading dose of pentobarbital is 5 mg/kg.[15] However, this dose is inadequate to achieve the serum concentrations (40 mg/L; 177 μmoL/L) necessary to induce an isoelectric EEG. Pentobarbital should be initiated with a loading dose of at least 10 to 20 mg/kg over 1 to 2 hours[24] (see Table 66–4). If hypotension occurs during the loading dose, the rate of administration should be slowed, or dopamine should be administered. The loading dose should be followed immediately by a continuous infusion.[15] Rates are typically begun at 1 mg/kg/h and titrated as needed up to a dose of 5 mg/kg/h. The maintenance infusion should be increased gradually until there is evidence of burst suppression on EEG (i.e., isoelectric EEG) or prohibitive adverse effects occur. Although the duration of barbiturate coma in most studies has been 2 to 3 days, it has been used safely for 53 days in

TABLE 66-4 Medications Used to Treat Refractory GCSE

	Loading Dose		Infusion Duration		Maintenance Dose	
Anticonvulsant (Route)	***Adult***	***Pediatric***	***Adult***	***Pediatric***	***Adult***	***Pediatric***
Lacosamide	200–300 mg	NA	3–5 min	NA	200 mg/d	NA
Levetiracetam IV	500–2,000 mg	15–70 mg/kg	33–66 mg/min	2–5 mg/kg/min	750–9,000 mg/d	20–60 mg/kg/d
Lidocaine IV	50–100 mg	1 mg/kg (max. dose = 3–5 mg/kg in first hour)	≤2 min	≤2 min	1.5–3.5 mg/kg/h	1.2–3 mg/kg/h
Midazolam IV	200 mcg/kg[a]	150 mcg/kg[a]	0.5–1 mg/min	0.5–1 mg/min	50–500 mcg/kg/h[b]	60–120 mcg/kg/h[b]
Pentobarbital IV	10–20 mg/kg	15–20 mg/kg	Over 1–2 h	Over 1–2 h	1–5 mg/kg/h[b]	1–5 mg/kg/h[b]
Propofol IV	2 mg/kg	3 mg/kg	Over 10 sec	Over 20–30 sec	5–10 mg/kg/h[b]	2–18 mg/kg/h[c]
Topiramate PO	300–1,600 mg	5–10 mg/kg	NA	NA	400–1,600 mg/d	5–10 mg/kg/d
Valproate IV	15–45 mg/kg	20–25 mg/kg	3 mg/kg/min	3 mg/kg/min	1–4 mg/kg/h[b]	1–4 mg/kg/h[b]

GCSE, generalized convulsive status epilepticus; NA, not available; PO, orally.
[a]Doses can be repeated twice every 10 to 15 minutes until the maximum dosage is given.
[b]Titrate dose as needed.
[c]Generally recommended not to exceed a dose of 4 mg/kg/h and a duration of 48 hours.

an 18-year-old patient.[28] To avoid complications (e.g., pneumonia, pulmonary edema), the pentobarbital should be discontinued as soon as possible. Twelve hours after a burst-suppression pattern is obtained, the rate of pentobarbital infusion should be titrated downward every 2 to 4 hours to enable the clinician to determine if the patient's GCSE is in remission. It is important to have other anticonvulsants at therapeutic amounts before pentobarbital is withdrawn so that the risk of seizure recurrence is minimized. Because pentobarbital is a potent hepatic enzyme inducer, doses of most concurrent anticonvulsants will need to be larger than usual maintenance doses. The patient will need to be monitored for side effects as deinduction occurs and anticonvulsant concentrations increase. This can take up to a month after pentobarbital's discontinuation.

Valproate

Although an IV dosage form has been approved by the FDA, it is not labeled for GCSE. A number of loading and continuous-infusion doses (see Table 66–4) have been used to treat GCSE in both adult and pediatric patients. Loading doses have ranged from 20 to 40 mg/kg.[25,29] Although the manufacturer originally recommended IV valproate be given no faster than 20 mg/min, much faster rates have been studied (40 mg/min; 2–10 mg/kg/min) and are used for administration of the loading dose.[25,29] The loading dose should be followed by a continuous or intermittent infusion. One study suggested the need to consider the effects of enzyme-inducing anticonvulsants when dosing and recommended that the continuous-infusion rate be determined by the presence of concurrent anticonvulsants (no inducers present, 1 mg/kg/h; one or more inducers [e.g., phenytoin, phenobarbital], 2 mg/kg/h; and inducers and pentobarbital coma, 4 mg/kg/h).[30]

In general, IV valproate has been well tolerated, with no cases of respiratory depression. Hemodynamic instability is extremely rare, but patients' vital signs should be monitored closely during the loading dose.

Propofol

Propofol is extremely lipid soluble, has a large volume of distribution, and has a very rapid onset of action. Its extremely short half-life promotes rapid awakening on drug discontinuation. Propofol's efficacy is comparable to midazolam for refractory GCSE.[24,31] Doses can be found in Table 66–4. Although controversial, it has been associated with progressive metabolic acidosis, hemodynamic instability, and bradyarrhythmias that maybe refractory to aggressive treatments.[32] Finally, a normal adult dose can provide over 1,000 calories (4186 J) per day as lipid at a cost to the patient that may exceed $800 per day.

Other Agents

In most reports, oral topiramate has been given in adults (300–1,600 mg/day) and in children (5–10 mg/kg/day).[13,25,33–36] Crushing the tablets and dissolving them in small amounts of water is necessary as no parenteral formulation is available. Doses as large as 25 mg/kg/day for 2 to 5 days have been used in children.[36] Response tends to be delayed hours to days. Because topiramate can induce metabolic acidosis and kidney stones, monitoring acid–base status and adequate hydration are recommended. Once seizures are controlled, doses should be tapered to a tolerable maintenance dose.

Oral doses of levetiracetam (750–9,000 mg/day) have been given in case series; however, doses larger than 3,000 mg/day do not add additional efficacy.[13,25,37] IV levetiracetam has begun to replace oral levetiracetam in refractory GCSE. Loading doses of up to 2,000 mg have been given to adults and up to 70 mg/kg in children.[38–40] Levetiracetam is not hepatically metabolized and is minimally protein bound, which makes drug–drug interactions unlikely. There have been two case reports of lacosamide used in refractory GCSE and NCSE.[41,42] Like levetiracetam, its lack of effect on the metabolism on other medications make it attractive for use. Neither levetiracetam nor lacosamide has been associated with toxicities (respiratory depression, hypotension) noted with the older anticonvulsants.

Lidocaine has been used in refractory GCSE, but its use is not recommended unless other agents have failed.[43] It is administered IV and has a rapid onset of action. Table 66–4 gives the recommended initial loading and continuous-infusion doses. Although the reference serum concentration range for the antiarrhythmic effects of lidocaine is 2 to 6 mg/L (8.5–25.6 μmol/L), the reference range for GCSE has not been established. Serum lidocaine concentrations should be monitored to avoid drug accumulation and toxicity. CNS toxicity (e.g., fasciculations, visual disturbances, and tinnitus) can occur at concentrations between 6 and 8 mg/L (25.6 to 34.2 μmol/L); seizures and obtundation can develop when concentrations exceed 8 mg/L (34.2 μmol/L).

Halothane, isoflurane, ketamine, and other inhaled anesthetics can produce EEG suppression; however, these gases are difficult to deliver outside the operating room and require an anesthesiologist. No proven advantages have been shown over traditional anticonvulsants (e.g., barbiturate coma or continuous-infusion benzodiazepine), and these gases can increase intracranial pressure. If used, dosing is titrated to obtain EEG burst suppression. Finally, it is also prudent to validate that the patient does not have a low serum-magnesium concentration, because magnesium deficiency can lower the seizure threshold.

PHARMACOECONOMIC CONSIDERATIONS

The estimated reimbursement for treatment of GCSE varies greatly based on the age of the individual and the GCSE etiology. A population study showed that the median reimbursement for GCSE was $8,417.[44] Median reimbursements were significantly greater for those 17 to 45 years of age ($14,689), those with acute CNS injury ($16,919), and those withdrawing from alcohol or anticonvulsants ($11,239). Lowest median reimbursements were found in those 0 to 16 years of age ($6,140) and those with non-CNS injury ($6,669). For patients with lengths of stay shorter than 1 week, the average reimbursement was $7,000 but increased to $32,907 if the stay was longer than 1 week. For patients staying 1 month or more, reimbursements were more than $60,000. Compared with other acute disorders (myocardial infarction, congestive heart failure, and intracranial hemorrhage), reimbursements for GCSE are 1.6- to 1.9-fold greater.

A number of economic issues can have an impact on formulary considerations. Clearly, there are intra- and interclass differences in medication costs and in ancillary tests or technologies associated with select therapies. For example, the average wholesale prices for seven therapies initiated in a patient weighing 70 kg (154 lb) are:

- Diazepam (20 mg) plus generic phenytoin (1 g): $14.68
- Lorazepam alone (8 mg): $6.72
- Midazolam alone (0.25 mg/kg load, 0.1 mg/kg/h): $51.34
- Generic phenytoin (1 g) alone: $14.34
- Diazepam (20 mg) plus fosphenytoin PE (1 g): $154.14
- Phenobarbital (20 mg/kg) alone: $35.15
- IV valproate (25 mg/kg load, 1 mg/kg/h): $123.00

Although many practitioners have heralded the arrival of fosphenytoin as an important therapeutic advancement, it has created a

fiscal and ethical dilemma for many institutions. Fosphenytoin is associated with less infusion pain and fewer IV-site complications and hemodynamic adverse effects than phenytoin; however, the cost of this agent ($149/g PE versus $14.47/g phenytoin) has caused many practitioners and administrators to struggle with the practical and ethical importance of the increased safety profile relative to the cost of the product to an institution. When evaluating the difference in cost of these two agents, it is important to remember that phenytoin requires the placement of two IV catheters because of its incompatibility with many solutions and medications that are given concurrently. Additionally, some practitioners are giving fosphenytoin intramuscularly in the emergency room for non-SE indications and thereby avoiding the placement of a catheter and use of an infusion device. Many institutions fail to consider the expense associated with a tissue infiltration of phenytoin, which can cause tissue necrosis that necessitates plastic surgery or amputation. The expense of a single multimillion-dollar lawsuit likely will offset the difference between phenytoin and fosphenytoin cost to several institutions.

There is little difference in expense if one advocates phenobarbital over midazolam as third-line therapy, but it might be argued that a patient who experiences phenobarbital-induced respiration depression ultimately may be more expensive to the healthcare system.

EVALUATION OF THERAPEUTIC OUTCOMES

Initial success is defined as termination of all clinical and electrical seizure activity, but ultimate success is measured by the patient's quality of life. The morbidity and mortality associated with GCSE are affected by the underlying etiology; however, these can be minimized by the rapid implementation of a rational therapeutic plan. An EEG is an extremely important tool that not only allows practitioners to determine when abnormal electrical activity has been aborted but also can assist in determining which anticonvulsant was effective. Because many of the anticonvulsants affect the cardiorespiratory system, it is imperative that vital signs (e.g., heart rate, respiratory rate, and blood pressure) be monitored during drug loading and infusion. Finally, it is imperative that the infusion site be assessed for any evidence of infiltration before and during administration of phenytoin. Information regarding the patient's past medical and drug history and imaging studies (e.g., MRI) also can help to determine if there is a defined etiology for the original episode of GCSE. This information then can be used to guide future medication therapy, as well as help in determining if the patient is at risk for a poor outcome.

CONCLUSION

Our understanding of the cellular basis, physiology, and neuropathology of GCSE continues to evolve. Over the past decade, research into an activated cascade of pathophysiologic changes in neurotransmission, GABAergic inhibition, and NMDA receptor channel—mediated events has enhanced our understanding of this disorder. Although anticonvulsants will continue to be the mainstay of therapy in terminating seizures, specific agents including antagonists of excitatory amino acid neurotransmitters (e.g., glutamate and calcium channel blockers) and agonists of inhibitory neurotransmitters (GABA) may help to block further neuronal damage beyond the epileptogenic focus. Likewise, additional trials investigating the role of newer anticonvulsants in GCSE are warranted.

ABBREVIATIONS

ALT: alanine aminotransferase

AMPA: α-amino-3-hydroxy-5-methyl-isoxazole-4-propionate

AST: aspartate aminotransferase

CBC: complete blood count

CNS: central nervous system

CT: computed tomography

ECG: electrocardiogram

EEG: electroencephalogram, electroencephalography

FDA: Food and Drug Administration

GABA: γ-aminobutyric acid

GCSE: generalized convulsive status epilepticus

MRI: magnetic resonance imaging

NCSE: nonconvulsive status epilepticus

NMDA: *N*-methyl-D-aspartate

SE: status epilepticus

CHAPTER 67

Acute Management of the Brain Injury Patient

BRADLEY A. BOUCHER AND SHELLY D. TIMMONS

KEY CONCEPTS

1. Cerebral ischemia is the key pathophysiologic event triggering secondary neuronal injury following severe traumatic brain injury (TBI). Intracellular accumulation of calcium is postulated to be a central pathophysiologic process in amplifying and perpetuating secondary neuronal injury via inhibition of cellular respiration and enzyme activation.
2. *Guidelines for the Management of Severe Brain Injury,* published by the Brain Trauma Foundation/American Association of Neurological Surgeons, serve as the foundation on which clinical decisions in managing adult neurotrauma patients are based; comparable guidelines for infants, children, and adolescents have also been published.
3. Correcting and preventing early hypotension (systolic blood pressure less than 90 mm Hg) and hypoxemia (Pa_{O_2} less than 60 mm Hg [8.0 kPa]) are primary goals during the initial resuscitative and intensive care of severe TBI patients.
4. The principal monitoring parameter for severe TBI patients within the intensive care environment is intracranial pressure (ICP). Cerebral perfusion pressure is also a critical monitoring parameter and should be maintained between 50 and 70 mm Hg (greater than 40 mm Hg in pediatric patients) through the use of fluids, vasopressors, and/or ICP normalization therapy.
5. Nonspecific pharmacologic treatment in the management of intracranial hypertension should include analgesics, sedatives, antipyretics, and paralytics under selected circumstances.
6. Specific pharmacologic treatment in the management of intracranial hypertension includes mannitol, furosemide, and high-dose pentobarbital. Neither routine use of corticosteroids nor aggressive hyperventilation (i.e., Pa_{CO_2} less than 25 mm Hg) should be used in the management of intracranial hypertension.
7. Phenytoin (or alternatively carbamazepine) should be used to prevent seizures in TBI patients at high risk for the first 7 days after injury. Use of phenytoin for the prophylaxis of posttraumatic seizures usually should be discontinued after 7 days if no seizures are observed.
8. Numerous investigational strategies (e.g., calcium antagonists, glutamate antagonists, antioxidants, free-radical scavengers, and progesterone) targeted at interrupting the pathophysiologic cascade of events occurring following severe TBI have been employed, but no proven therapeutic benefits have been identified.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Traumatic brain injury (TBI) is currently the leading cause of death and disability among children and young adults in the industrialized world.[1,2] A focus on TBI prevention, and improved acute care and rehabilitation must remain national priorties.[2] This chapter summarizes TBI epidemiology and pathophysiology, and highlights the major guidelines and systematic reviews of the literature pertaining to the management of severe TBI patients.

EPIDEMIOLOGY

It is estimated that approximately 1.4 million persons sustain a TBI each year in the United States.[1] Among these individuals, 235,000 require hospital admission and 50,000 die annually.[2] Importantly, over 5.3 million Americans currently live with disabilities as a result of their TBI, highlighting the enormous physical and emotional toll of this healthcare problem.[2] The economic effects of acute neurotrauma are also enormous, with estimates of spending on TBI patients requiring hospitalization of $60 billion in the United States in 2000.[3] Economic costs to society from lost productivity are also massive, especially considering the young age of many TBI patients.[4] Falls are the leading cause of TBI (28%) while motor vehicle accidents result in the greatest number of TBI-related hospitalizations and deaths overall.[2] Death rates from TBI are highest in patients 75 years of age or older.[2] TBI-related mortality in males has been reported to exceed that in females three-fold.[2] However, recent data suggest that female mortality may actually exceed the mortality rate in males in postmenopausal women.[5]

PRIMARY AND SECONDARY BRAIN INJURY PATHOPHYSIOLOGY

The neurologic sequelae of brain trauma can occur instantaneously as a consequence of the primary injury or can result from secondary injuries that follow within minutes, hours, or days.[1] Primary injury involves the external transfer of kinetic energy to various structural components of the brain (e.g., neurons, nerve synapses, glial cells, axons, and cerebral blood vessels). The biomechanical forces responsible for primary brain injury can be classified broadly as contact (e.g., blunt-object blow, penetrating-missile

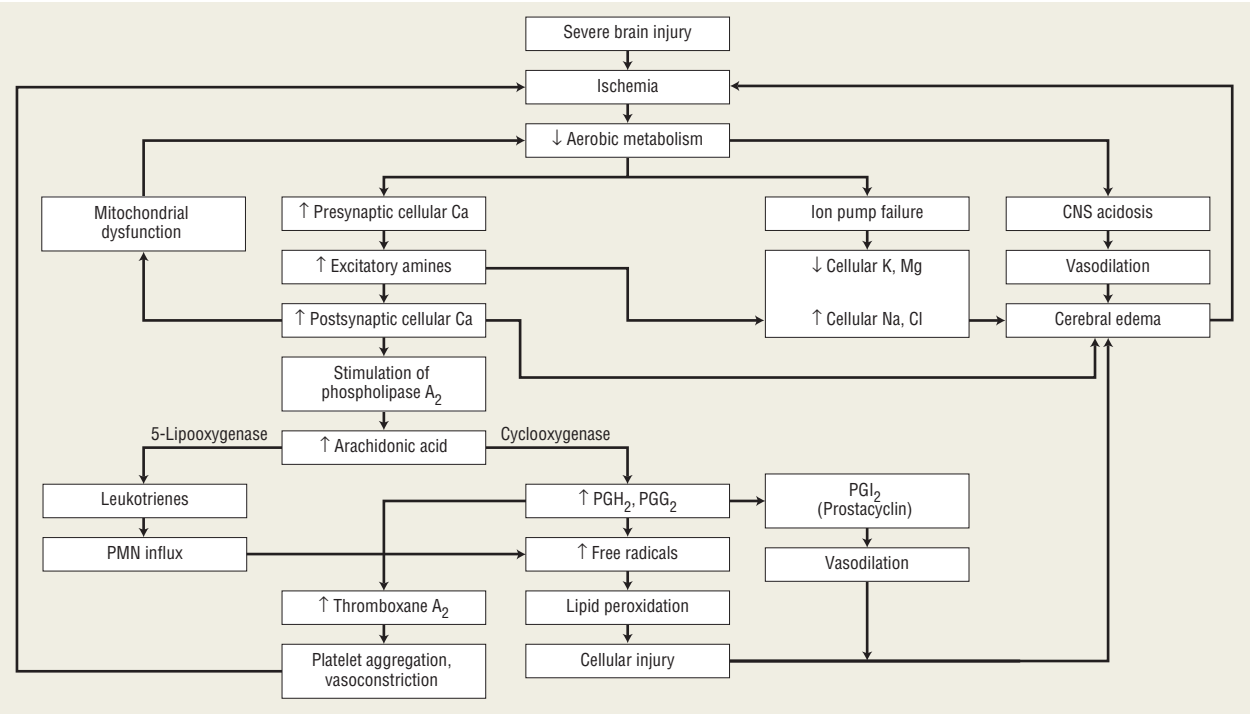

FIGURE 67-1. Schematic illustration of the cascade of biochemical events proposed to occur following severe neurotrauma (secondary brain injury). (Ca, calcium; CNS, central nervous system; K, potassium; Mg, magnesium; Na, sodium; Cl, chloride; PMN, polymorphonucleocyte; PG, prostaglandin.)

injuries) and acceleration/deceleration (e.g., instantaneous brain movements following motor vehicle accidents).[1] Primary injuries are categorized further as focal (e.g., contusions, hematomas) or diffuse.[4] The latter usually are associated with shearing or stretch forces, which primarily affect axons within the brain (i.e., diffuse axonal injury).[6] The type of primary injury (i.e., focal versus diffuse) is a major factor as to which of the secondary injury mechanisms discussed below will predominate following a TBI; however, many patients, especially those involved in high-speed accidents sustain both types of injury.[7]

1 A complex sequence of pathophysiologic events precipitated by primary brain injury may seriously disrupt the normal central nervous system (CNS) balance between oxygen supply and demand.[7] Hypotension during the early posttraumatic period is a major contributor to this imbalance and a primary determinant of outcome.[1,6] The end result of this imbalance may be cerebral ischemia, the key pathophysiologic event triggering secondary injury.[7,8] Figure 67–1 is a simplified schematic of the processes that constitute secondary brain injury and their various interrelationships. The brain is particularly susceptible to ischemia because of its normally high resting energy requirement and its limited capacity to store oxygen, glucose, and adenosine triphosphate (ATP).[8] Ischemia following brain injury typically occurs in the first 6 to 24 hours following the insult.[9] Thereafter, patients can have hyperemia from days 1 to 3.[9] Vasospasm also can occur in approximately one fourth to one third of TBI patients.[6] These phenomena can result in imbalances in cerebral oxygen delivery (CDo_2) and consumption ($CMRo_2$), processes that are closely autoregulated under normal circumstances. Factors that can diminish cerebral oxygen supply following brain injury include cerebral edema, expanding mass lesions (e.g., epidural, subdural, and intracerebral hematomas), cerebral vasospasm, and loss of vasoregulatory control. Vasogenic cerebral edema can develop as a consequence of cerebral capillary endothelial damage and disruption of the blood-brain barrier.[7,8] Cytotoxic cerebral edema is a consequence of loss of cell wall integrity that accompanies ischemia or hypoxia.[8] With cytotoxic and vasogenic edema comes expansion of the intracellular and extracellular fluid spaces, respectively. Elevated intracranial pressure (ICP) is the most detrimental consequence of cerebral edema formation and occurs as the brain tissue volume increases within the nondistensible skull. A significant increase in ICP may further compromise cerebral blood flow (CBF) and extend cytotoxic edema. Hence an increase in ICP can be self-perpetuating unless this cycle is reversed. Hypoxemia can further exacerbate local decreases in cerebral oxygen supply following acute respiratory failure and systemic hypotension. Metabolic demand also can increase following neurotrauma secondary to seizures, agitation, and temperature elevation.[8] Brain tissue affected by focal ischemia can have a dense core surrounded by a marginally viable region.[8] If adequate CBF is restored, the affected tissue may recover; however, sustained ischemia can result in further loss of cellular integrity and eventual cell death.

The two distinctive end points along the spectrum of secondary neuronal injury are (1) cellular necrosis characterized by cell membrane lysis, edema, and inflammation; and (2) apoptosis which leads to cell shrinkage and cell membrane dissolution.[7,8] Apoptosis which is also known as programmed cell death requires a cascade of intracellular events for completion of cell death.[7] The loss of ionic homeostasis is postulated to be a key event in fostering secondary brain injury following cerebral ischemia. Cellular influx of sodium, chloride, and water with a corresponding efflux of potassium and magnesium occurs secondary to cytotoxic edema and Na^+-K^+-ATPase pump dysfunction.[7,8] An influx of calcium into the presynaptic terminal ends of damaged neurons is mediated by N-type voltage-sensitive calcium channels. This influx is postulated to stimulate excessive release of the excitatory amines glutamate and aspartate from the affected neurons. These amines then accumulate in the neuronal synaptic cleft in the presence of cellular energy failure.[8] The result is ongoing stimulation of postsynaptic cells, which can result in an extension of neuro-

toxicity and cell death. Influx of calcium and additional sodium is stimulated by activation of ionophore receptors including the *N*-methyl-*D*-aspartate (NMDA) receptor.[7,8] Calcium influx and its intracellular accumulation initiate a number of events that amplify and perpetuate secondary neuronal injury. High intracellular concentrations of calcium result in mitochondrial dysfunction, which further inhibits cellular respiration, a process already affected by ischemic and/or hypoxic insults.[7] A second major deleterious effect of calcium is to stimulate activation of autodestructive enzymes, including phospholipases, endonucleases, and proteases, such as the caspase family of enzymes.[7,8] The effect of phospholipase A_2 stimulation includes formation of several arachidonic acid metabolites derived from membrane lipids: thromboxane A_2, prostaglandins, and leukotrienes.[7,8] The subsequent effects of these metabolites are lipid peroxidation and the formation of reactive oxygen species.[1,7,8] Recent data suggest that this event occurs very early after injury (e.g., before hospitalization), which may limit the effectiveness of exogenously administered antioxidants.[10]

Cell-mediated injury involving inflammatory mediators (e.g., proinflammatory cytokines) and nitric oxide activation is yet another possible mechanism involved in secondary neuronal injury.[7] Among the cell lines implicated are polymorphonuclear neutrophils, platelets, endothelial cells, and macrophages. Noteworthy is that limited data suggest that activation of some inflammatory mediators may actually be beneficial such that the relative balance of the mediators versus absolute concentrations may be the most significant pathophysiologic factor following TBI.[11] Stimulation of platelet aggregation, vasodilation, and vasoconstriction, intravascularly, also may occur. Lastly, data suggest that there may be a genetic vulnerability to the effects of TBI.[12,13] For example, preliminary evidence indicates that this may be related to faster recovery of aspartate uptake from the cerebral spinal fluid (CSF) and the CSF lactate/pyruvate ratio in TBI patients in the absence of the apolipoprotein E4 allele.[14] The latter is the same protein that has been associated with the deleterious effects of various types of Alzheimer disease.[14]

CLINICAL PRESENTATION OF ACUTE BRAIN INJURY

General

- Level of consciousness on admission ranges from awake and alert to completely unresponsive (i.e., GCS 15 to 3, respectively).

Symptoms

- Posttraumatic amnesia (e.g., >1 hour), increasing dizziness, a moderate to severe headache, nausea/vomiting, limb weakness, or paresthesia may indicate more severe injury.

Signs

- CSF otorrhea or rhinorrhea, and seizures may indicate more severe injury.
- A rapid deterioration in mental status strongly suggests the presence of an expanding lesion within the skull.
- Severe TBI may be accompanied by significant alterations or instability in vital signs, including abnormal breathing patterns (e.g., apnea, Cheyne-Stokes respiration, tachypnea), hypertension, or bradycardia.

Laboratory Tests

- ABGs indicating hypoxia (i.e., decreased Pao_2) or hypercapnia (i.e., increased $Paco_2$) may indicate compromised ventilation.
- A positive blood ethanol concentration and/or positive urine drug screen indicates that drug intoxication may be affecting the patient's mental status in addition to the TBI.
- Electrolyte disturbances can cause alterations in mental status, and their effects may interfere with assessment of neurological status relative to brain lesion.

Other Diganostic Tests

- CT of the head is an important diagnostic tool for detecting the presence of mass lesions.

GCS, Glasgow Coma Scale; CSF, cerebrospinal fluid; TBI, traumatic brain injury; ABG, arterial blood gas; Pao_2, partial pressure of arterial blood oxygen; $Paco_2$, partial pressure of arterial blood carbon dioxide; CT, computed tomography.

CLINICAL PRESENTATION

The Glasgow Coma Scale (GCS) is the most widely used system to grade arousal and the functional capacity of the cerebral cortex.[6] The GCS defines the level of consciousness according to eye opening, motor response, and verbal response (Table 67–1). A GCS score of 15 corresponds to a normal neurologic examination. A GCS score of 3–8, 9–12, and 13–15 is consistent with severe, moderate, and mild brain injury, respectively.[6] The possibility of ethanol or drug intoxication, hypotension, hypoxia, postictal state, or hypothermia altering the neurologic examination always should be considered. Because narcotics and muscle relaxants affect the neurologic examination, they should not be administered until the initial examination is complete if at all possible. Simple, rapidly attainable clinical variables that are predictive of survival include patient age, GCS score (especially the motor score), pupillary reactivity, presence or absence of a hematoma, subarachnoid hemorrhage, midline shift, and appearance of the ventricular cisterns found on a computed tomographic (CT) scan of the head.[15]

TABLE 67-1 Glasgow Coma Scale

Response	Score
Eyes	
Open spontaneously	4
To verbal command	3
To pain	2
No response	1
Best motor response	
To verbal command	
Obeys	6
To painful stimulus (pressure to nailbeds)	
Localizes pain	5
Flexion, withdrawal	4
Flexion, abnormal (decorticate rigidity)	3
Extension (decerebrate rigidity)	2
No response	1
Best verbal response	
(arouse patient with painful stimulus if necessary)	
Oriented and converses	5
Disoriented and converses	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1
Total	3–15

TREATMENT

General Traumatic Brain Injury Treatment Principles

2 In July 1995, the Brain Trauma Foundation (BTF) published an extensive document entitled *Guidelines for the Management of Severe Brain Injury* as a joint initiative with the Guidelines Committee of the American Association of Neurological Surgeons (AANS) and the Joint Section on Neurotrauma and Critical Care of the AANS and the Congress of Neurological Surgeons, with subsequent revision in 2000.[16] A third revision was released in 2007.[17] This landmark publication constitutes the most widely accepted series of evidence-based standards, guidelines, and options for the care of severe TBI patients. As important are the data documenting that compliance with the BTF/AANS guidelines can result in improved outcomes relative to mortality rate, functional outcome scores, length of hospitalization, and cost.[18] Since then, guidelines addressing prehospital TBI management,[19] surgical management,[20] and management of penetrating brain injury have been published. Furthermore, TBI management guidelines for infants, children, and adolescents have been developed.[21] In addition, a series of systematic reviews addressing TBI management emanating from the Cochrane Library has been published.[22–27] These reviews have rigorously evaluated the literature for essentially all the major conventional TBI treatment strategies. The recommendations emanating from the published guidelines on TBI management and published systematic reviews will be highlighted throughout the remaining portion of this chapter. Until further clinical studies become available, recommendations from the published guidelines should serve as the foundation on which all clinical decisions in managing severe TBI are based. Nonetheless, it should be noted that the majority of the guidelines are based on class II evidence (primarily prospective clinical trials) and class III evidence (primarily retrospective clinical trials). Few class I evidence studies (i.e., prospective, randomized, controlled trials) are available for traumatic brain injury. The pharmacologic management of TBI is summarized in Table 67–2. Recommendations provided in this chapter pertain to adults and children unless specifically noted to the contrary.

TABLE 67-2 Pharmacologic Management of Traumatic Brain Injury

Hyperosmolar therapy
Mannitol is effective for control of increased intracranial pressure at doses of 0.25 g/kg to 1 g/kg body weight. (Evidence Level II)
Infection prophylaxis
Periprocedural antibiotics for intubation should be administered to reduce the incidence of pneumonia. (based largely on a single study). (Evidence Level II)
Routine prophylactic antibiotic use for ventricular catheter placement is not recommended to reduce infection. (Evidence Level III)
Deep venous thrombosis prophylaxis
Low molecular weight heparin or low dose unfractionated heparin should be used in combination with mechanical prophylaxis. However, there is an increased risk of expansion of intracranial hemorrhage. (Evidence Level III)
Anesthetics, analgesics, and sedatives
Prophylactic administration of barbiturates to reduce burst suppression (electroencephalogram is not recommended). (Evidence Level II)
High-dose barbiturate administration is recommended to control elevated ICP refractory to maximum standard medical and surgical treatment. Hemodynamic stability is essential before and after barbiturate therapy. (Evidence Level II)
Propofol is recommended for the control of ICP, but does not improve mortality or 6-month outcome. High-dose propofol can produce significant morbidity. (Evidence Level II)
Antiseizure prophylaxis
Prophylactic use of phenytoin or valproate is not recommended for preventing late PTS (greater than 7 days). (Evidence Level II)
Anticonvulsants are indicated to decrease the incidence of early PTS (within 7 days of injury) in high risk patients. (Evidence Level II)
Corticosteroids
The use of steroids is not recommended for improving outcome or reducing intracranial pressure. In patients with moderate or severe TBI, high-dose methylprednisolone is associated with increased mortality and is contraindicated. (Evidence Level II)

Evidence Level I. Good quality randomized controlled trial (RCT).
Evidence Level II. Moderate quality RCT; good quality cohort; good quality case-control.
Evidence Level III. Poor quality RCT; moderate or poor quality cohort; moderate or poor quality case control; case series, databases, or registries.
ICP, intracranial pressure; TBI, traumatic brain injury; PTS, posttraumatic seizures.
Data from Bratton et al.[17]

DESIRED OUTCOMES

The overall goal in TBI management is not only reduction in morbidity and mortality but also optimization of long-term functional outcome for these patients. This requires careful attention to the following short-term therapeutic goals: (1) establishment of an adequate airway and maintenance of ventilation and circulation during the initial period of resuscitation and evaluation, (2) maintenance of balance between CDo_2 and $CMRo_2$, (3) prevention or attenuation of secondary neuronal injury, and (4) prevention and/or treatment of associated medical complications.

INITIAL RESUSCITATION

The first priority in the unconscious patient is the establishment of an airway, which ensures adequate oxygenation and prevents aspiration.[6,28] 3 Thereafter, restoration of circulating blood volume and maintenance of systolic arterial pressure (SBP) greater than 90 mm Hg are of utmost importance.[1,17] In pediatric patients, the SBP goal should be greater than 70 mm Hg + (2 × age in years).[21] Correcting and preventing early hypotension (SBP less than 90 mm Hg) and hypoxia (Pao_2 less than 60 mm Hg [8.0 kPa]) are essential because these two factors are among the most powerful predictors of outcome.[17] Isotonic saline (0.9% normal saline) and lactated Ringer's solution have been traditionally used as initial resuscitation fluids of choice in TBI patients.[16] However, some clinicians believe that hypertonic saline (e.g., 3% or 7.5% saline) is beneficial in the resuscitation of TBI patients.[29] Clinical studies have yielded equivocal results relative to superiority over isotonic solutions.[1,30,31] Regardless, no clear consensus exists as to the optimal initial resuscitation fluid. While albumin therapy may be considered as an alternative to crystalloid fluid resuscitation, a retrospective analysis of 460 TBI patients revealed an increase in mortality (33.2%) compared with those patients receiving 0.9% normal saline.[32] Vasopressors and inotropic agents may be needed to maintain an adequate mean arterial pressure (MAP) if hypotension persists after adequate restoration of intravascular volume. Figure 67–2 is an algorithm summarizing treatment priorities in the initial management of acute TBI.

POSTRESUSCITATIVE CARE

Following successful resuscitation, priorities shift toward diagnostic evaluation of intracranial and extracranial injuries and emergent surgical intervention as needed. Evacuation of intracranial hematomas (i.e., epidural, subdural, and intracerebral hematomas) is essential to control ICP and improve outcome. Elevation of depressed skull fractures and débridement of penetrating wound tracts are other important emergent surgical procedures in TBI patients.

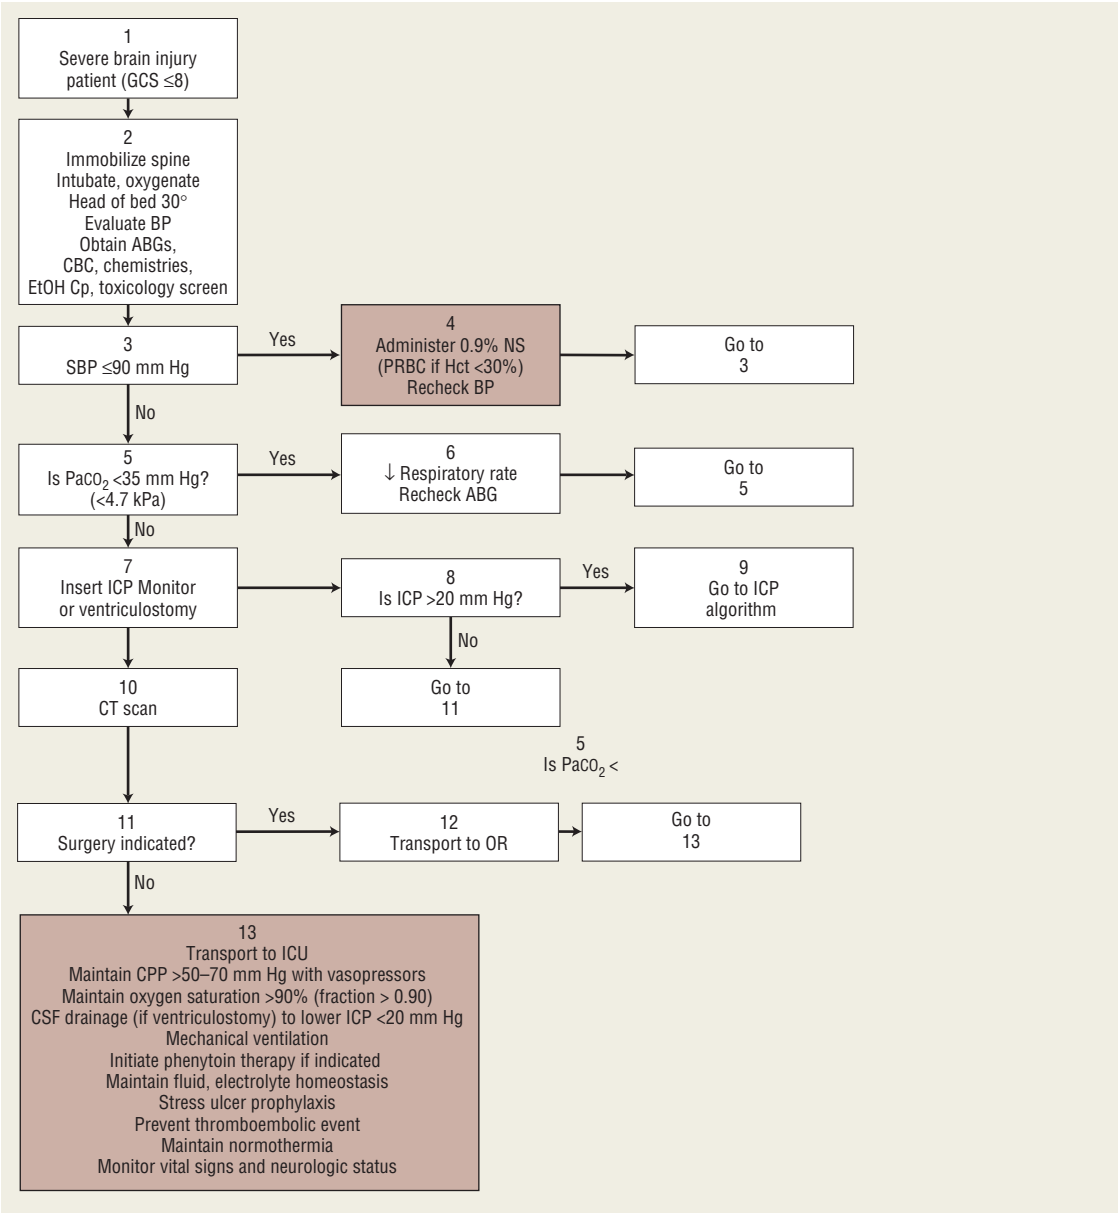

FIGURE 67-2. Algorithm for the acute management of the TBI patient. (GCS, Glasgow coma scale; BP, blood pressure; ABG, arterial blood gas; CBC, complete blood count; EtOH Cp, ethanol plasma concentration; SBP, systolic blood pressure; NS, normal saline; PRBC, packed red blood cells; Hct, hematocrit, $Paco_2$, partial pressure of arterial blood carbon dioxide; ICP, intracranial pressure; CT, computed tomography; OR, operating room; ICU, intensive care unit; CPP, cerebral perfusion pressure; CSF, cerebral spinal fluid.) *(Reprinted with permission from Boucher BA. Neurotrauma. In Carter BL, Angaran DM, Lake KD, Raebel MA, eds. Pharmacotherapy Self Assessment Program, 2nd ed. Critical Care Module. Kansas City, MO: American College of Clinical Pharmacy, 1995:220).*

Decompressive craniectomies (i.e., removal of variable amount of skull bone) with or without temporal or frontal lobectomy may be considered in patients with increases in ICP refractory to more conservative measures.[1] The beneficial effects of routine decompressive surgery in adult TBI patients to date are controversial.[33] Nonetheless, decompressive surgery in pediatric patients has generally yielded more favorable outcomes.[33] 4 Continuous ICP monitoring (e.g., intraventricular catheter, intraparenchymal fiberoptic catheter) is indicated in salvageable patients with a GCS score of 3 to 8 after resuscitation with an abnormal admission CT scan, or in high-risk severe TBI patients with a normal CT scan who meet two of the following criteria: age older than 40 years, motor posturing, SBP less than 90 mm Hg.[17] Intraventricular catheters have a therapeutic advantage over the other alternatives but are associated with a higher complication rate and can be difficult to place in the setting of the swollen brain. Specifically, CSF can be drained using this device as a means to lower ICP.[1] Continuous ICP monitoring is the only means to objectively evaluate the success of therapies used to decrease ICP. When the ICP exceeds 20 to 25 mm Hg, therapy should be initiated to decrease ICP below 20 mm Hg.[17,21] While used extensively in TBI patients and advocated within consensus guidelines, the need for a prospective, randomized, controlled trial to further define its value has recently been suggested.[34,35] Jugular venous oxygen saturation ($Sjvo_2$) monitoring is advocated by some practitioners for detection of global cerebral hypoxia (i.e., adequacy of CBF relative to $CMRo_2$), although it is technically difficult to achieve consistent results.[8,36] Hence its role remains confined predominantly to use in academic centers and for research.[8,36] The use of brain tissue oxygen monitoring may prove to be a superior alternative to $Sjvo_2$ to evaluate oxygen diffusion in TBI patients.[8,37]

Cerebral microdialysis is yet antoher technique that has been used successfully as a research tool to measure the cerebral extracellular chemistry of TBI patients.[8,38] Biochemical markers (e.g., S-100 protein) have been suggested as having utility relative to monitoring TBI patients.[39] However, no clear role has yet to be defined for such markers, especially since there may be incongruence between serum and brain concentrations of proteins such as S-100.[40]

4 Another important monitoring parameter for severe TBI patients within the intensive care environment is the cerebral perfusion pressure (CPP). The CPP is the difference between MAP and ICP (i.e., CPP = MAP − ICP). Maintenance of an acceptable CPP has been postulated to be critical in reducing cerebral ischemia and secondary injury. The BTF/AANS guidelines recommend maintaining a range of CPP between 50 and 70 mm Hg and specifically indicate avoiding CPP values less than 50 mm Hg.[17] Current guidelines also recommend that aggressive attempts to maintain CPP greater than 70 mm Hg in adults should be avoided because of the risk of the acute respiratory distress syndrome.[17] In children, the recommended CPP goal is greater than 40 mm Hg.[21] Despite being commonly used, the optimal approach to CPP management continues to be debated.[41]

The goal CPP can be achieved by increasing MAP through the use of fluids and/or vasopressors or by lowering elevated ICP. The goal of volume expansion should be euvolemia as well as avoidance of a hypoosmolar state and negative fluid balance.[21,30] If the hematocrit is below 30%, transfusion of packed red blood cells (PRBCs) is indicated.[1] However, recent evidence cautions against the liberal use of blood in TBI and other critically ill patients secondary to worse outcomes associated with their use.[42] Volume status should be targeted to a central venous pressure of 7 to 12 cm H_2O if invasive monitoring is employed.[1] After achievement of euvolemia, the patient's head should be elevated at 30 degrees to promote venous drainage and decrease ICP. If restoration of the intravascular volume is inadequate in elevating MAP to an acceptable level, hypertension should be induced using vasopressors or inotropic support. The drugs employed most commonly to induce hypertension are dopamine, phenylephrine, and norepinephrine.[1] Patients should be monitored for renal dysfunction, lactic acidosis, and signs of peripheral ischemia when these agents are used, especially at large doses.

Treatment of Intracranial Hypertension

GENERAL PHARMACOLOGIC STRATEGIES

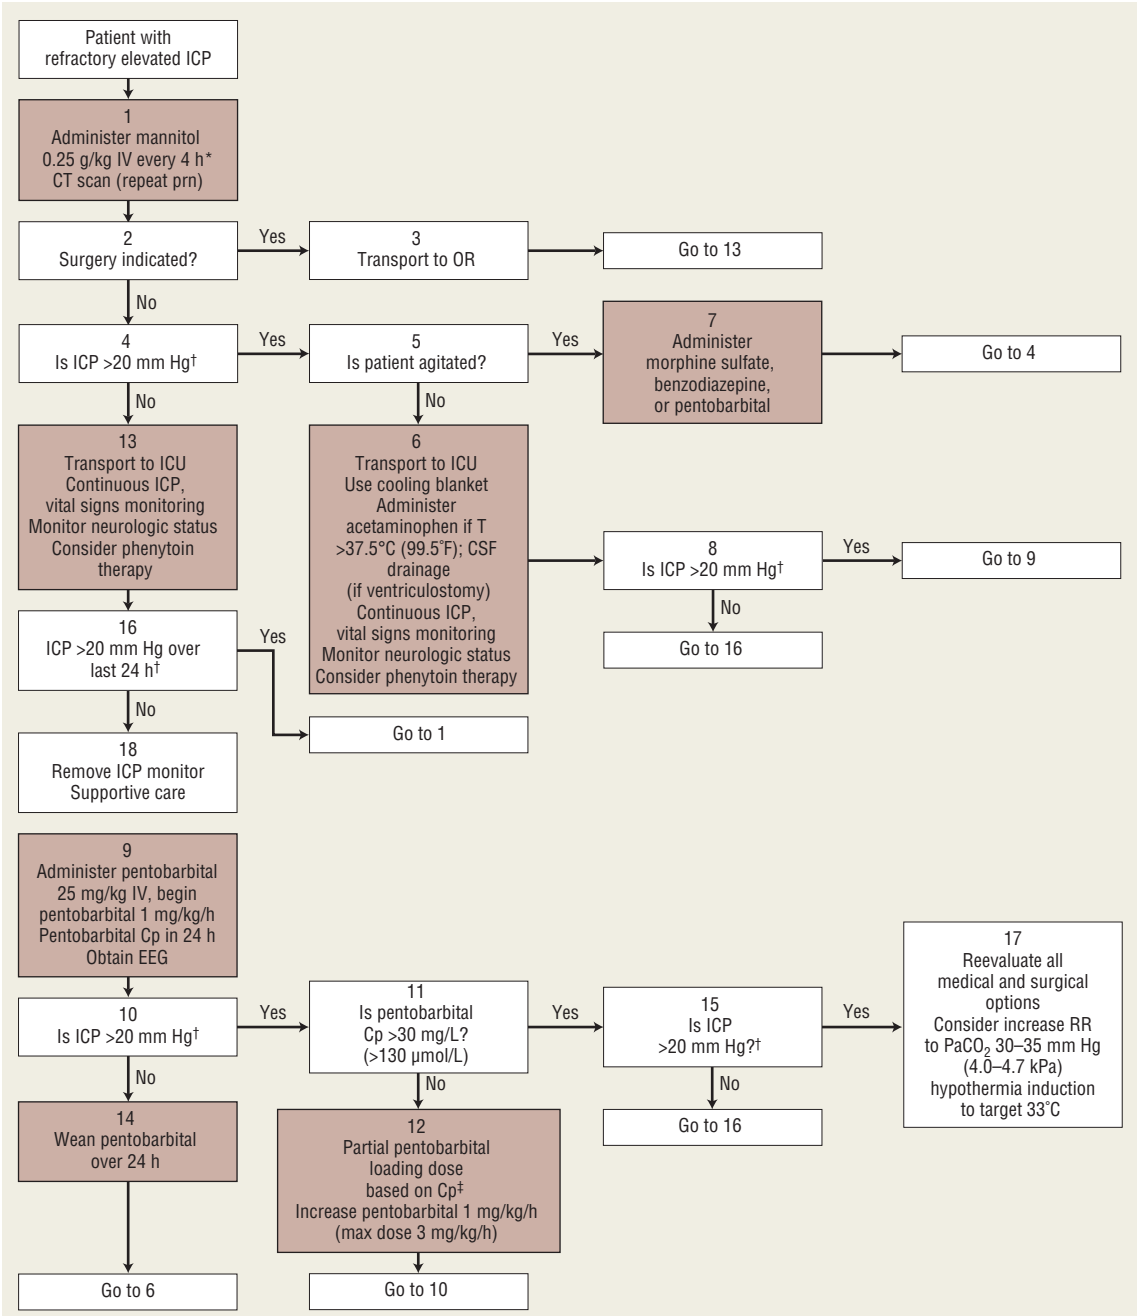
5 The use of analgesics, sedatives, and paralytics has an important primary role in the management of intracranial hypertension (Fig. 67–3).[43] This is related directly to the association of pain, agitation, excessive muscle movement, and resisting mechanical ventilation with transient increases in ICP. Nonetheless, there have been no studies of the effect of sedation on outcome in patients with severe TBI.[17] Morphine sulfate is the most commonly used analgesic and sedative in this setting.[17] While fentanyl and sufentanil are gaining in popularity, their use may be associated with mild elevations in ICP.[17] Propofol has become the sedative of choice in TBI patients among many clinicians because of its ease of titration, rapidly reversible effects on discontinuation, and possible neuroprotective effects.[17] Although it is used for sedation in infants and children who are mechanically ventilated in the ICU setting, the Food and Drug Administration (FDA) requires that the manufacturer labeling contain specific information that propofol is not approved for sedation of pediatric patients admitted to an ICU. One of the biggest safety concerns with the use of propofol is the propofol infusion syndrome (PIS) characterized by hyperkalemia, hepatomegaly, lipemia, metabolic acidosis, myocardial failure rhabdomyolysis, renal failure, and death in some cases.[17,44] While inititally reported in children, PIS can also occur in adults. Doses greater than 5 mg/kg/hour and infusion exceeding 48 hours should be used with extreme caution.[17] Triglyceride concentrations also should be monitored in patients receiving prolonged propofol infusions and/or high dosages of propofol considering its lipid emulsion formulation and the potential for inducing hypertriglyceridemia under these conditions. Alternative sedatives include etomidate (particularly useful in rapid-induction anesthesia), intermittent low-dose pentobarbital, and short-acting benzodiazepines (e.g., midazolam), especially if there is a reasonable suspicion of alcohol withdrawal as the underlying etiology of the agitation. The potential for these agents to decrease MAP and CPP must be monitored closely. Additionally, the cumulative sedative effects of longer-acting drugs, especially benzodiazepines, must be taken into account. The use of any sedative agent also must be weighed against its potential to obscure the neurologic examination of the patient. Interference with the neurologic examination is also associated with paralytic agents.

HYPERVENTILATION

6 The practice of prolonged aggressive hyperventilation ($Paco_2$ less than 25 mm Hg [3.3 kPa]) to decrease ICP is no longer recommended.[17] Hyperventilation acutely decreases systemic and cerebral $Paco_2$. The resulting hypocapnia, in turn, induces cerebral vasoconstriction, thereby decreasing CBF and cerebral blood volume (CBV).[8] For decades, it was a widely held belief that a reduction in CBV and any accompanying decrease in ICP were beneficial. Nonetheless, a systematic review of the literature concluded that data are inadequate to ascertain potential benefit or harm from hyperventilation.[25] Hyperventilation should be avoided during the first 24 hours following acute TBI when CBF is often critically reduced according to the most current BTF/AANS guidelines.[17] Hyperventilation for brief periods may nonetheless be considered as a temporary maneuver in the setting of refractory intracranial hypertension or in the initial management of patients with signs of cerebral herniation.[17,21] If hypoventilation is performed, the use of $Sjvo_2$ or cerebral tissue oxygen perfusion monitoring is recommended.[17]

HYPOTHERMIA

While hypothermia has been discussed for nearly 50 years as a cerebral protective maneuver in TBI patients, a resurgence of interest has been fueled by the results of several preliminary studies in the early 1990s demonstrating trends in improvement in mortality and morbidity rates in severe TBI patients randomized to receive mild to moderate hypothermia. However, in the most extensive investigation to date, TBI patients randomized to receive hypothermia (n = 199) within 6 hours of injury (target body temperature 33°C [91.4°F]) and maintained for 48 hours did not have significantly improved outcomes at 6 months compared with a normothermia group of TBI patients (n = 196).[45] The BTF/AANS guidelines concur with these findings that prophylactic hypothermia is not significantly associated with decreased mortality when compared with normothermic controls.[17,46] A recent meta-analysis confirms these results, concluding that hypothermia is not beneficial in the management of TBI patients.[26] Nonetheless, the guidelines leave open the possibility that there may be a mortality benefit if this therapeutic maneuver is continued for more than 48 hours.[17,46] Depth of hypothermia, as well as the rate of rewarming after discontinuation of hypothermia, are additional factors that may affect outcomes with this therapeutic maneuver in TBI patients.[47,48] The mechanism underlying a protective effect of hypothermia is likely



* Alternatively 150 ml 7.5% hypertonic saline. Hold if serum osmolality >320 mOsm/kg (>320 mmol/kg)

† Treatment thresholds: ICP 20–29 mm Hg for >15 min
ICP 30–39 mm Hg for >2 min
ICP ≥40 mm Hg for >1 min

Note: Transient ICP increases may occur following respiratory procedures (e.g., suctioning, chest physiotherapy, bronchoscopy, intubation).

Kansas City, MO: American College of Clinical Pharmacy, 1995:224–225).*

multifactorial, although a reduction in $CMRo_2$ is offered most frequently as the basis of any therapeutic benefits. Potential side effects of hypothermia include coagulation disturbances, infectious complications, and cardiac arrhythmias.[46,47] An increase in ICP also may occur secondary to hypothermia-associated shivering that can be prevented with neuromuscular blocking agents. Unfortunately, these agents are also associated with potential adverse events. Considering these latter risks and equivocal data from clinical trials

to date, hypothermia should continue to be considered an investigational treatment.[26]

OSMOTIC AGENTS

6 Although a number of osmotic diuretics (e.g., urea, glycerol) can be used to decrease ICP, mannitol is unquestionably the most widely employed.[1,17] Despite the common practice of administering mannitol to patients with suspected or actual increases in ICP following brain injury, no clinical trial comparing its effects against placebo have been performed.[27] The mechanisms responsible for mannitol's beneficial effects likely relate to (1) an immediate plasma-expanding effect that reduces blood viscosity and increases CBF and (2) establishment of an osmotic concentration gradient across an intact blood-brain barrier that decreases ICP as water diffuses from the brain into the intravascular compartment.[17] Recommended doses of mannitol typically range from 0.25 to 1 g/kg intravenously every 4 hours.[17] Increased ICP is reduced within minutes following mannitol administration, and the duration of action ranges from 90 minutes to 6 hours depending on the dose and the clinical conditions that are present.[17] In order to maximize benefit and minimize adverse events, it was previously recommended that mannitol be administered as a bolus and not as a continuous infusion in this setting.[1,16] However, recent analyses conclude that neither administration approach has a demonstrable superiority.[17,49]

Several adverse effects are associated with mannitol. In addition to hypotension resulting from its diuretic effect, a reversible acute renal dysfunction may occur in patients with previously normal renal function after long-term, large-dose administration, especially if the serum osmolality or serum sodium exceed 320 mOsm/kg (mmol/kg) and 160 mEq/L (mmol/L), respectively.[1] Hence monitoring and maintaining the serum osmolality and sodium, and replacing urinary fluid losses are important to minimize this adverse event. Mannitol should be avoided in patients with renal failure.[21] Acute exacerbation of underlying congestive heart failure and pulmonary edema also may occur following rapid intravascular volume expansion. Furosemide is recommended as an alternative diuretic for lowering ICP in these latter patient groups.

As previously mentioned, hypertonic saline solutions have been advocated as a resuscitative fluid following TBI. Hypertonic solutions ranging from concentrations of 3% to 23.4% have also been used to acutely lower increased ICP.[28,31] Not only do hypertonic saline solutions create an osmotic gradient in favor of reducing cerebral edema, but recent evidence suggests that they may also have beneficial vasoregulatory, immunologic, and neurochemical effects as well.[11] A comparison of isovolume 20% mannitol versus 7.5% hypertonic saline in 20 TBI patients refractory to nonspecific therapy (i.e., sedation, analgesia, body positioning) demonstrated significant improvement in the duration and number of elevated ICP episodes per day in those treated with 7.5% hypertonic saline.[50] No differences in mortality or functional outcome were observed in this study between the two patient groups. However, a recent study of equimolar doses of mannitol versus 7.45% hypertonic saline revealed similar effects between the two regimens in 20 TBI patients.[51] As such, demonstration of definitive superiority of hypertonic saline therapy compared with osmotic diuretics will require further investigation.

BARBITURATES

6 High-dose barbiturate therapy (i.e., *barbiturate coma*) has been used for decades in the management of increased ICP, despite a lack of evidence documenting beneficial effects on patient morbidity and mortality.[24] Nonetheless, based largely on beneficial outcomes observed in a randomized clinical trial published in 1988, BTF/AANS and pediatric guidelines recommend that high-dose barbiturate therapy be considered in hemodynamically stable severe TBI patients refractory to maximal medical ICP-lowering therapy and decompressive surgery.[17,21] Prophylactic use of barbiturates is not advocated in light of insufficient evidence supporting this practice and the potential for adverse events (e.g., hypotension).[17,21,24] Several mechanisms responsible for the cerebral protective effects of barbiturates have been proposed. These include (1) lowering the regional $CMRo_2$ with a coupled reduction in CBF to these areas, (2) inhibition of lipid peroxidation, and (3) alteration of cerebral vascular tone.[1,43] Prior to inducing a barbiturate coma, the severe TBI patient must be mechanically ventilated with continuous monitoring of arterial blood pressure, electrocardiogram (ECG), and ICP. Pentobarbital is the most commonly used barbiturate for this indication, although thiopental also has been used. Pentobarbital should be administered as an intravenous loading infusion totaling 25 mg/kg (i.e., 10 mg/kg over 30 minutes and then 5 mg/kg per hour for 3 hours), followed by a maintenance infusion of 1 to 2 mg/kg per hour.[1,17] If the systolic blood pressure falls during the loading or maintenance infusions, the rate should be slowed temporarily and blood pressure support initiated. The goal of a barbiturate coma is to maintain ICP and CPP at the previously discussed target thresholds in addition to achieving a pentobarbital steady-state concentration of between 30 and 40 mcg/mL (30 and 40 mg/L; 133 and 177 μmol/L) (despite poor correlation between serum concentrations and outcome) and EEG burst suppression.[17] Initiation of barbiturate therapy discontinuation can occur when ICP has been controlled satisfactorily for 24 to 48 hours. Barbiturates should be tapered over 24 to 72 hours to prevent ICP spikes.

Side effects associated with high-dose barbiturate therapy involve primarily the cardiovascular system. Hypotension caused by peripheral vasodilation may occur, necessitating decreasing the barbiturate dose or the administration of fluids and vasopressors to maintain blood pressure. A recent systematic review of the literature suggested that one of every four patients receiving barbiturate therapy will develop hypotension.[24] Gastrointestinal (GI) effects of barbiturates include decreased GI muscular tone and decreased amplitude of contraction. On emergence from coma, there may be a period of GI hypermotility. Care should be taken to avoid extravasation of pentobarbital and thiopental solutions because severe tissue damage may occur. Barbiturates should be administered by continuous infusion through a central line dedicated for this purpose. The potential for barbiturates to induce the hepatic metabolism of concurrent medications should be also considered. Lastly, the potential for prolonged interference with the proclamation of brain death in TBI patients meeting the locally accepted brain death neurologic criteria must be considered prior to the initiation of high-dose barbiturate therapy.

CORTICOSTEROIDS

6 Although corticosteroids are effective in preventing or reducing cerebral edema in patients with nontraumatic conditions producing vasogenic edema, studies in TBI patients have not demonstrated the ability to lower ICP or improve outcome.[17,22] Specifically, use of corticosteroids following TBI has been associated with increased mortality and complications, including GI bleeding, glucose intolerance, electrolyte abnormalities, and infection. The largest investigation to date was known as the CRASH (Corticosteroid Randomization After Significant Head Injury) study.[52] In this study, 10,008 patients with a GCS score less than or equal to 14 were randomized to receive a 48-hour continuous infusion of methylprednisolone or placebo. Results of this study indicated a higher risk of death within 2 weeks of enrollment (relative risk 1.18) in those patients receiving corticosteroids compared with patients receiving placebo

(P <0.001).[52] Based on this and several other major randomized trials, the BTF/AANS adult and pediatric guidelines recommend that high-dose corticosteroids not be used in patients with moderate to severe TBI.[17,21]

Treatment and Prophylaxis of Complications

POSTTRAUMATIC SEIZURES

It is generally agreed that patients who have experienced one or more seizures following a moderate to severe TBI should receive anticonvulsant therapy to avoid increases in $CMRO_2$ that occur with the onset of subsequent seizures and to prevent the development of (sometimes subclinical) status epilepticus with associated increase in mortality. Initial therapy in these persons should consist of incremental intravenous doses of diazepam (5–40 mg for adults, 0.1–0.5 mg/kg for infants and children) or lorazepam (2–8 mg for adults, 0.03–0.1 mg/kg for infants and children) to terminate any active seizure activity followed by intravenous phenytoin to prevent seizure recurrence. Phenytoin dosing regimens for adults and pediatric patients include an intravenous loading dose of 15 to 20 and 10 to15 mg/kg, respectively, followed by a maintenance dose of 5 mg/kg/day. Alternatively, fosphenytoin, a water-soluble phosphate ester of phenytoin, can be administered intravenously or intramuscularly using the same doses, specified as phenytoin equivalents (PE). The merits of preventive anticonvulsant therapy in patients who have not had a seizure postinjury historically have been more controversial. Risk factors for early posttraumatic seizures (less than 7 days after injury) include a GCS score of less than 10, a cortical contusion, a depressed skull fracture, a subdural hematoma, an epidural hematoma, an intracerebral hematoma, a penetrating head wound, or a seizure within the first 24 hours of injury.[17] In a landmark randomized, placebo-controlled study, the incidence of early posttraumatic seizures in patients receiving placebo was 14.2% compared with 3.6% in patients receiving phenytoin (P < 0.05) without a significant increase in drug-related side effects.[53] 7 A systematic review of the literature corroborated these findings, estimating an improved pooled relative risk for early seizure prevention of 0.34 (95% confidence interval, 0.21–0.54) in patients receiving anticonvulsants.[54] Thus it is recommended that phenytoin (or alternatively carbamazepine) should be used to prevent seizures in TBI patients at high risk for the first 7 days after injury.[17,21,55] Valproate therapy is not recommended based on a trend for higher mortality in a study comparing valproate-treated patients with those receiving phenytoin short-term therapy.[53] The benefits of prophylactic anticonvulsants beyond 7 days have not been demonstrated, and thus their use for this indication beyond 7 days is not recommended.[17,54] Unfortunately, despite reducing the incidence of early seizures following brain injury, no beneficial effects have been documented for anticonvulsants on patient mortality or long-term disability.[17,53,54] This is particularly disconcerting considering that the long-term risk of epilepsy after TBI has been documented to be increased up to 10 years or longer based on results of a recent population-based cohort study.[56]

CLINICAL CONTROVERSY

Persistant hyperglycemia may be an independent predictor of higher mortality in TBI patients. As such, tight glucose control may improve outcome in TBI patients. However, some authorities suggest that this practice is unproven and unsafe after brain injury

SUPPORTIVE CARE

While normalizing ICP and maintaining an adequate CPP are the highest priorities in preventing secondary injury following severe TBI, attention also must be given to preventing and/or treating systemic and extracranial complications.[17,21] This includes careful ongoing fluid and electrolyte management.[31] Common electrolyte disturbances in TBI patients that should be monitored and treated aggressively include hyponatremia, hypomagnesemia, hypokalemia, and hypophosphatemia. Aggressive nutritional support of the TBI patient is another important therapeutic consideration.[16,21] Evidence suggests that early feeding of TBI patients (i.e., by 7 days) may be associated with a trend toward better outcomes in terms of survival and disability.[17,57,58] Infectious complications commonly encountered in severe TBI patients include nosocomial pneumonia, sepsis, urinary tract infections, and meningitis.[1] Treatment of these potentially devastating infections should be aggressive, with careful attention being paid to antibiotic blood–brain barrier penetration for intracranial infections. Hyperthermia also should be avoided in TBI patients because patients with elevated temperatures have poorer outcomes than normothermic patients.[1,21,59] Hence aggressive maintenance of a core temperature of less than 37.5°C (99.5°F) using acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), and cooling blankets is indicated for patients following severe TBI. Several experimental cooling techniques, including intravascular cooling for use in TBI patients refractory to conventional management strategies, were discussed in a recent review of this topic.[59] Other important therapeutic interventions include acute gastritis prophylaxis, and prevention of decubiti and contractures. Prevention of thromboembolic events is also an extremely important component of supportive care in TBI patients since the incidence of a deep venous thrombosis is higher in TBI patients compared with patients without brain injury.[1,60] This can be accomplished with the use of graduated compression stockings or intermittent pneumatic compression devices initially. Thereafter, systemic therapy (e.g., low-molecular-weight heparin) should generally be initiated within 2 to 3 days in combination with the mechanical devices until patients are ambulatory.[17,61] However, systemic anticoagulation must be used with caution in those patients with intracerebral hemorrhage, or in patients who may need to undergo craniotomy early in their course. Monitoring for a coagulopathy is important in any severe TBI patient since the incidence is high (greater than 30%), and coagulopathy is associated with a significantly longer ICU length of stay and an almost 10-fold increase in mortality based on data from a recent study.[62] Reversal of coagulopathy with recombinant factor VIIa in critically ill trauma patients with TBI is gaining in popularity among some physicians despite lacking an approved indication or large clinical trials demonstrating its safety and efficacy in TBI patients.[63,64]

CLINICAL CONTROVERSY

Off-label use of recombinant factor VII is advocated by some neurosurgeons for managing life-treatening intracranial hemorrhage in TBI patients. The potential for thromoembolic events using this procoagulant must be considered as part of any cost versus benefit analysis in these patients.

CLINICAL PATHWAYS/GUIDELINE IMPLEMENTATION

Use of clinical pathways and formal TBI management guidelines has been demonstrated to improve TBI patient outcomes and reduce institutional resource utilization as summarized in a current review.[65]

The magnitude of these improvements is revealed in a recent single center study in which patients with a good recovery or moderate disability increased from 50.3% to 61.5%, and charges for care were reduced by greater than $8,000.[18] Few practitioners would dispute the overall importance of integrating current evidence-based management guidelines into clinical practice as a means to optimize care and improve the functional outcome of TBI patients.[66]

INVESTIGATIONAL THERAPY

8 The steady decrease in morbidity and mortality following severe neurotrauma over the last 30 years can be attributed largely to expeditious and aggressive management of events resulting in secondary injury (i.e., ischemia, hypoxia, increased ICP) using conventional treatment strategies. Numerous neuroprotective agents targeting specific pathophysiologic processes that are theorized to occur following severe TBI have been investigated over the last decade in an attempt to further enhance the prospects for a meaningful recovery. Prominent among these strategies have been attempts to modulate calcium influx through the administration of calcium antagonists[23,67,68] and glutamate antagonists including magnesium,[67,69–73] and the use of antioxidants/free-radical scavengers.[67] Inhibitors of inflammatory mediators also are under consideration as neuroprotective agents.[74] Unfortunately, none of these agents to date has demonstrated a significant reduction in morbidity or mortality following severe TBI in phase III clinical trials. Noteworthy is that a phase II pilot study recently demonstrated a decrease in mortality in 100 TBI patients randomized to receive a 3-day infusion of progesterone compared with placebo.[75] A follow-up, independently conducted, double-blinded clinical trial of progesterone in 159 TBI patients also improved outcome at 6 months postinjury,[76] prompting experts to call for a phase III trial of this promising pharmacologic strategy.[77] Other neuroprotective strategies use growth factors, including brain-derived neurotrophic factor and nerve growth factor,[78] that may have a future role in the management of TBI by promoting nerve cell regeneration and differentiation.[74] Such neurorestorative strategies can be classified as structural or functional. Lastly, there are miscellaneous agents including calpain inhibitors, inhibitors of caspases (enzymes involved in apoptosis) including erythropoietin and the antiinflammatory agent, minocycline, that are being considered as viable neuroprotective agents based on experimental TBI studies.[71,78,79] Despite generally negative clinical trial findings to date, the search is likely to continue for neuroprotective agents including those with multiple pathophysiologic targets that eventually may improve the long-term outcome in severe TBI patients.[80]

CLINICAL CONTROVERSY

A growing body of evidence from a small number of studies suggests that beta-blocker use may improve survival following TBI. Mechanistically, these benefits may be realized through reversal of a hyperadrenergic state often associated with TBI. A major concern with their use is the potential to reduce systemic blood pressure.

OTHER TREATMENT STRATEGIES

The concept of administering commercially available CNS active agents for nonapproved indications in TBI patients should presently be considered investigative therapy. One example is the use of CNS stimulants in the management and rehabilitation of TBI patients. A comprehensive review of the use of methylphenidate relative to improving cognition following TBI was recently conducted. It was the opinion of the author that the literature does provide a degree of support for improvements in memory, attention, concentration, and mental processing in this patient subset, although results and study designs were highly variable for those investigations included in the analysis.[81] Another example is the use of Parkinson disease medications (e.g., amantidine, bromocriptine, carbidopa/levodopa) in severe TBI patients in an attempt to enhance dopamine release and inhibit reuptake within the injured region of the brain. A review of amantidine following TBI indicated that improved cognition and arousal were evident in the majority of patients studied.[82] Cholinergic agents such as donepezil have also undergone limited investigation in TBI patients.[83] Antidepressants represent yet another class of agents that has been studied in TBI patients.[83] While intuitively appealing, routine administration of psychostimulants to improve cognitive outcomes in TBI patients or drugs that enhance the biochemical milieu within the CNS following a TBI should be undertaken cautiously until large, well-controlled studies demonstrating beneficial effects are available. Additionally, the timing of administration of these drugs is controversial; the potential for cardiovascular side effects in the face of uncertain benefit would indicate that these drugs should be reserved for the postacute phase of treatment (i.e., weeks to months postinjury).

EVALUATION OF THERAPEUTIC OUTCOMES

The process for evaluation of therapeutic outcomes is summarized in Table 67–3. Patients with severe TBI require ICU monitoring initially with the goals of maintaining or reestablishing

TABLE 67-3 Evaluation of Therapeutic Outcomes

General	GCS: Record hourly initially, decrease frequency as neurologic status stabilizes
	Vital signs (BP, HR, RR, temperature): Record hourly initially, decrease frequency as neurologic status stabilizes
	Urine output: Record hourly initially, decrease frequency as neurologic status stabilizes
	Arterial oxygen saturation: Continuously while in intensive care unit
Risk of increased ICP	ICP: Record hourly, decrease frequency as ICP stabilizes <20 mm Hg (usually not until 48–72 hours postinjury at a minimum)
	CPP: Record hourly, decrease frequency as CPP stabilizes in the desired range[a]
Laboratory tests	Blood ethanol concentration and urine drug screen: On admission
	ABGs: Daily at a minimum while intubated, repeated as needed based on pulmonary instability requiring ventilator setting changes
	CBC: Daily while in intensive care unit
	Serum electrolytes (Na, K, Cl): Daily while in intensive care unit. Serum sodium and osmolality may be monitored as frequently as every six hours if osmotherapy (mannitol, furosemide, hypertonic saline) is being utilized
	Minerals (Mg, Ca, P): Daily initially until concentrations stable
Radiologic procedures	CT scan: Postresuscitation initially with repeat scan(s) as needed based on degree of neurologic instability (e.g., decrease in GCS) or initial CT appearance

GCS, Glasgow Coma Scale; BP, blood pressure; HR, heart rate; RR, respiratory rate; CSF, cerebrospinal fluid; TBI, traumatic brain injury; ICP, intracranial pressure; CPP, cerebral perfusion pressure; ABG, arterial blood gas; CBC, complete blood count; Na, sodium; K, potassium; Cl, chloride; Mg, magnesium; Ca, calcium; P, phosphorus; CT, computed tomography.

[a]Continuous monitoring mandated initially if technologically feasible.

neurologic and systemic homeostasis as well as readily detecting any neurologic deterioration. This requires frequent evaluation of the patient's neurologic status (e.g., GCS) and measurement of vital signs, urine output, and arterial oxygen saturation (as well as ICP in patients with an ICP monitor in place). Furthermore, careful attention must be paid to the potential for a variety of electrolyte, mineral, and acid-base disturbances, coagulopathies, and infections by obtaining various laboratory tests on a daily basis initially. The intensity of monitoring will be a function of the relative degree of neurologic and hemodynamic stability of the patient in the hours and days following the neurologic insult. Lastly, radiologic tests (e.g., CT scans) are essential not only for the initial diagnostic evaluation of TBI patients but also as means to evaluate the etiology for any subsequent neurologic deterioration as well.

CHAPTER 68

Parkinson's Disease

JACK J. CHEN, MERLIN V. NELSON, AND DAVID M. SWOPE

KEY CONCEPTS

1. Thoughtful consideration for selection of initial therapy, management of drug dosing, and use of adjunctive therapies throughout the course of idiopathic Parkinson's disease (IPD) is necessary to optimize long-term therapeutic outcomes and minimize adverse effects.
2. The optimal time to start drug therapy in IPD varies, but in general, treatment should be initiated when the disease begins to interfere with activities of daily living, employment, or quality of life. However, in the absence of functional impairment, rasagiline may be offered.
3. Anticholinergic medication is useful for mild tremor-predominant IPD but should be used with caution in the elderly and in those with preexisting cognitive difficulties.
4. As monotherapy, amantadine and monoamine oxidase type B (MAO-B) inhibitors provide benefits in early IPD, but the symptomatic effect is less than that of dopamine agonists and carbidopa/levodopa (L-dopa).
5. Carbidopa/L-dopa is the most effective medication for symptomatic treatment and eventually all patients with IPD will require it.
6. Most carbidopa/L-dopa–treated patients will develop motor complications (e.g., fluctuations and dyskinesias).
7. MAO-B inhibitors and catechol-*O*-methyl-transferase inhibitors attenuate motor fluctuations in carbidopa/L-dopa–treated patients.
8. Dopamine agonists are effective and, compared to L-dopa, associated with less risk of developing motor complications but more likely to cause psychiatric symptoms, such as hallucinations and impulse control disorders.
9. Surgery is reserved for patients who require additional symptomatic relief or control of motor complications despite receiving medically optimized therapy.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

The presence of tremor at rest, rigidity, bradykinesia, and postural instability (instability of balance) are considered the hallmark motor features of idiopathic Parkinson's disease (IPD). These clinical features of IPD were adeptly described in 1817 by James Parkinson.[1]

EPIDEMIOLOGY

Up to 1 million individuals in the United States have IPD. The approximate annual incidence of IPD (i.e., number of persons diagnosed with IPD per year) is age-dependent and ranges from 10 per 100,000 persons in the sixth decade of life (i.e., 50–59 years of age) to 120 per 100,000 persons in the ninth decade of life (i.e., 80–89 years of age).[2,3] Likewise, the prevalence of IPD also increases with age, affecting 1% of people older than age 65 years and 2.5% of those older than age 80 years. The usual age at time of diagnosis ranges between 55 and 65 years. A higher incidence is reported among males, with a male-to-female ratio of up to 2:1.

ETIOLOGY

The true etiology of IPD is unknown, but is likely the result of interactions between aging, genetic constitution, and environmental factors. In IPD, a key histopathologic feature is degeneration of dopaminergic neurons in the substantia nigra that project to the striatum (i.e., the nigrostriatal pathway).[4] Additionally, neuronal vulnerability in IPD extends beyond the nigrostriatal pathway and includes specific neurons in autonomic ganglia, basal ganglia, spinal cord, and neocortex.[5] In humans and primates, administration of the compound 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) results in a form of parkinsonism. The MPTP compound is converted by monoamine oxidase (MAO)-B to 1-methyl-4-phenylpyridinium ion (MPP^+), a potent neurotoxin. MPP^+ is toxic to neurons by inhibiting mitochondrial complex 1 of the electron transport chain, which results in the generation of excessive reactive oxygen species and cell death.[6] Several synthetic pesticides have a molecular structure similar to that of MPTP. Although IPD is sporadic, extensive epidemiologic research associates environmental factors, such as chronic exposure to pesticides and heavy metals (such as iron and manganese), rural living, and drinking well water, with a risk for lifetime development of IPD.[7–10] Interestingly, epidemiologic studies have consistently associated an inverse correlation between cigarette smoking and caffeine consumption for development of IPD.[11,12]

Intrinsically, the substantia nigra pars compacta (SNc) is a region characterized by high levels of oxidative stress because free radicals are generated from dopamine autooxidation mediated by MAO (Fig. 68–1). Several antioxidative molecules (e.g., glutathione) are present in the SNc to limit damage produced by free-radical attack,

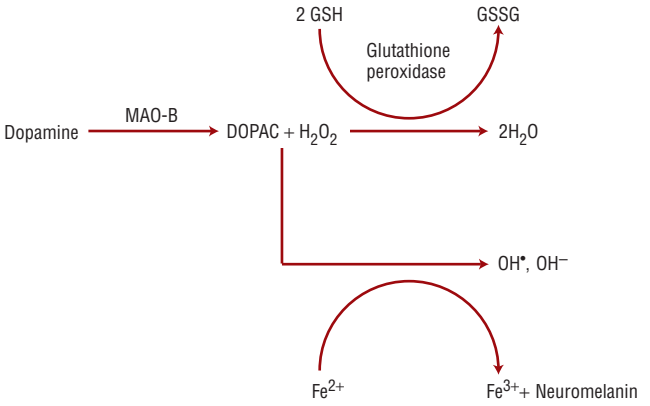

FIGURE 68-1. Dopamine metabolism results in hydrogen peroxide (H_2O_2) formation. If the glutathione system is deficient or excess hydrogen peroxide is present, hydrogen peroxide accepts an electron from ferrous iron (Fe^{2+}), forming ferric iron (Fe^{3+}) and the hydroxyl free radical (OH^*). The hydroxyl free radical can cause lipid peroxidation, thereby damaging neuronal cell membranes. (DOPAC, 3,4-dihydroxyphenylacetic acid; GSH, glutathione; GSSG, glutathione disulfide; H_2O, water; OH, the hydroxide ion; MAO-B, monoamine oxidase B.)

but in IPD, such protection might be overwhelmed or impaired. Thus cellular damage from oxidant stress has long been discussed as an etiopathologic component of IPD.[13] The SNc is also rich in iron and copper, essential cofactors in the biosynthesis and metabolism of dopamine. The oxidation–reduction cycle of iron can also generate free radicals and toxic metabolites (Fig. 68–1). In addition, apoptosis (programmed cell death), excitotoxicity, inflammation, mitochondrial dysfunction, nitric oxide toxicity, proteosomal dysfunction, and autophagic cellular mechanisms are also implicated etiopathologic mechanisms in IPD.

Genetics may play a significant role, particularly if IPD begins before age 50 years.[14,15] More than a dozen gene mutations are associated with forms of parkinsonism. For example, autosomal dominant forms of parkinsonism are associated with mutations of the α-synuclein (*PARK1* and *PARK4*) and *leucine-rich repeat kinase 2* (*LRRK*) genes. Autosomal recessive forms are associated with mutations of *parkin (PARK2)* and *PTEN-induced putative kinase 1 (PINK1)* genes. Overall, these forms of genetically linked parkinsonisms constitute only a small percentage of total parkinsonism cases and their pathology and phenotypic aspects differ from that of IPD.

PATHOPHYSIOLOGY

In the SNc, the two hallmark histopathologic features of IPD are depigmentation of dopamine-producing neurons (i.e., loss of SNc neurons) and presence of Lewy bodies (neuronal cytoplasmic filamentous aggregates composed of the presynaptic protein α-synuclein) in the remaining SNc neurons. Lewy bodies appear in degenerating neurons in association with adjacent gliosis. Lewy pathology has been proposed to develop in a predictable anatomic distribution within the parkinsonian brain.[5] In the premotor stage of IPD, Lewy bodies are initially found in the medulla oblongata, locus coeruleus, raphe nuclei, and olfactory bulb. This may correlate with observations that anxiety, depression, and impaired olfaction is detectable in premotor stages of IPD. As IPD progresses, Lewy pathology ascends to the midbrain (particularly the SNc) and accounts for development of motor features. In advanced stages, Lewy pathology spreads to the cortex, and this may correlate with cognitive and additional behavior changes. The observation that Lewy pathology can spread into adjacent healthy neurons has given rise to the postulate that prion-like propagation of α-synuclein aggregates may be occuring.

Pathologic findings reveal a correlation between the extent of nigrostriatal dopamine loss and the severity of certain IPD motor features (e.g., bradykinesia). The threshold for onset of clinically detectable IPD appears to be the loss of 70% to 80% of SNc neurons.[16] Functional neuroimaging studies suggest compensatory responses, such as upregulation of dopamine synthesis and downregulation of synaptic dopamine reuptake, occur as adaptive mechanisms beginning in the premotor stage of IPD. These adaptive responses may help to explain why the motor features are not clinically detectable until profound depletion (70%–80%) of SNc neurons has occurred.

Dopaminergic projections from the SNc to the striatum (putamen and caudate) synapse on two major populations of dopamine receptor-mediated efferent neurons (referred to as the direct and indirect pathways), which, in turn, mediate motor activity via a complex neuronal circuit involving the extrapyramidal system (Fig. 68–2). In IPD, the degeneration of the SNc neurons results in reduced activity within these two efferent pathways. The direct pathway involves activation of striatal dopamine$_1$ (D_1) dopamine receptors (which are coupled to adenylate cyclase) and stimulates

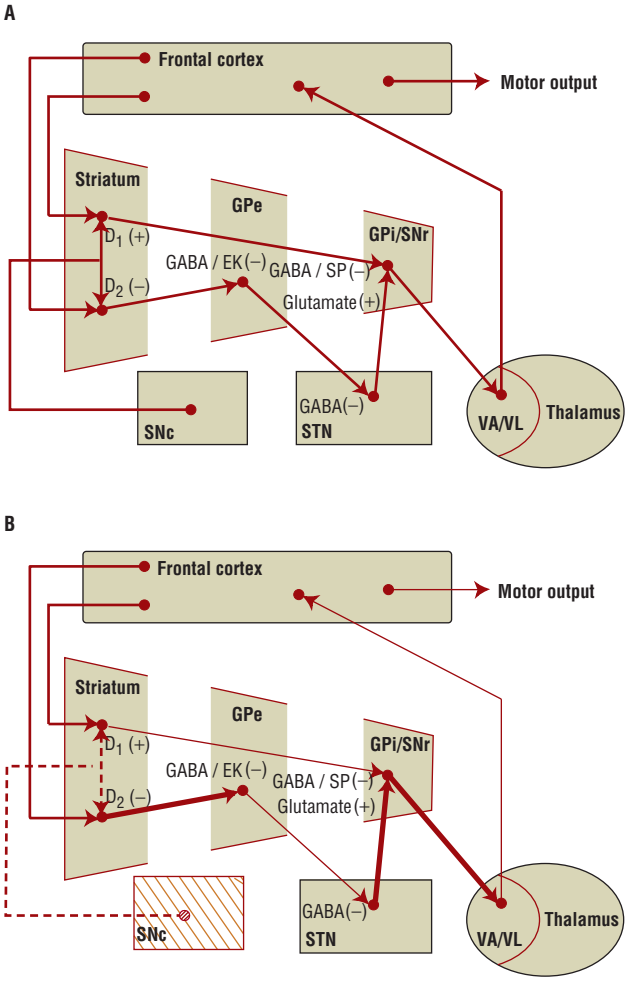

FIGURE 68-2. *A.* The normal balance of the basal ganglia–thalamocortical circuit. *B.* With nigrostriatal degeneration *(dashed line)*, there is loss of inhibition of the GPi by the direct pathway and activation of the GPi via the indirect pathway, resulting in decreased activation of the cortex. See text for details. (GPe, globus pallidus externa; GPi, globus pallidus interna; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; STN, subthalamic nucleus; VA, ventroanterior nuclei of the thalamus; VL, ventrolateral nuclei of the thalamus.)

the inhibitory γ-aminobutyric acid (GABA)/substance P efferents to the globus pallidus interna (GPi) and substantia nigra pars reticulata. The GPi and substantia nigra pars reticulata efferents are inhibitory to the thalamus.[17] In IPD, the reduced activation of D_1 receptors results in greater inhibition of the thalamus. The indirect pathway involves activation of striatal dopamine$_2$ (D_2) dopamine receptors (which are coupled to a guanosine triphosphate-binding protein that opens potassium channels to hyperpolarize neurons, thereby reducing the excitability of the neuron).[17] Activation of striatal D_2 receptors inhibits GABA/enkephalin efferents (medium spiny neurons) to the globus pallidus externa. The globus pallidus externa projects GABA neurons to the subthalamic nucleus. Here, excitatory glutamatergic neurons project to the GPi. GPi output is inhibitory on the glutamatergic thalamic projections. In IPD, the reduced activation of D_2 receptors translates into greater inhibition of the thalamus. In IPD, restoring activity at the D_2 receptor appears to be of more importance than the D_1 receptor for mediating clinical improvements. Overall, loss of the presynaptic nigrostriatal dopamine neurons in IPD results in inhibition of thalamic activity and reduced activation of the motor cortex. Dopaminergic therapies help to restore motor activity.

In addition to dopamine, the synaptic organization of the basal ganglia also involves a variety of other neurotransmitters and neuromodulators, including acetylcholine, adenosine, enkephalins, GABA, glutamate, serotonin, and substance P. The potential role for drug modulation of these other neurotransmitters and receptor types is an active area of research and novel drug discovery for IPD.[18]

Atypical parkinsonian disorders, such as multiple system atrophy and progressive supranuclear palsy are characterized by damage to postsynaptic striatal neurons and dopamine receptors. Dopaminergic therapies provide less robust efficacy in atypical parkinsonism.

CLINICAL PRESENTATION

Although IPD is unmistakable in its advanced form, recognizing IPD during the early stages can be challenging. Clinically probable IPD can be diagnosed when at least two of the following are present: limb muscle rigidity, resting tremor (at 3–6 Hz and abolished by movement), or bradykinesia (Table 68–1).[19] Asymmetry in the presence or severity of these motor features is also a conspicuous finding. Overall, a diagnosis of IPD can be made with a high level of confidence in a patient who has resting tremor (along with bradykinesia and/or rigidity), prominent asymmetry, and a good response to dopaminergic therapy. For the diagnosis of IPD, other conditions must be reasonably excluded (Table 68–1). Medication-induced parkinsonism can mimic IPD, so it is important to establish if such medications have been used (especially drugs that block D_2 receptors, such as antipsychotics, metoclopramide, or phenothiazine antiemetics). Neurologic conditions that can be mistaken for IPD include atypical parkinsonisms (e.g., corticobasal ganglionic degeneration, forms of multiple system atrophy, progressive supranuclear palsy) and essential tremor. Because the management and prognosis of IPD differs from these other conditions, an accurate diagnosis is important. When the diagnosis is in doubt, referral to a movement disorders specialist is recommended.

PRESENTATION OF IDIOPATHIC PARKINSON'S DISEASE

General Features

- For clinically probable IPD, the patient exhibits at least two of the following: resting tremor, rigidity, or bradykinesia. Asymmetric onset and severity of these features is typical.
- Postural instability (difficulty with maintaining balance) is more common in advanced IPD.

Motor Symptoms

- The patient experiences decreased manual dexterity, difficulty arising from a seated position, diminished arm swing during ambulation, dysarthria (slurred speech), dysphagia (difficulty with swallowing), festinating gait (tendency to pass from a walking to a running pace), flexed posture (axial, upper/lower extremities), "freezing" at initiation of movement, hypomimia (reduced facial animation), hypophonia (reduced voice volume), and micrographia (diminution of handwritten letters/symbols) (Fig. 68–3).

Autonomic and Sensory Symptoms

- The patient experiences bladder and anal sphincter disturbances, constipation, diaphoresis, fatigue, olfactory disturbance, orthostatic blood pressure changes, pain, paresthesia, paroxysmal vascular flushing, seborrhea, sexual dysfunction, and sialorrhea (drooling).

Mental Status Changes

- The patient experiences anxiety, apathy, bradyphrenia (slowness of thought processes), confusional state, dementia, depression, hallucinosis/psychosis (typically drug induced), and sleep disorders (excessive daytime sleepiness, insomnia, obstructive sleep apnea, and rapid eye movement sleep behavior disorder).

Laboratory Tests

- No laboratory tests are available to diagnose IPD.

Other Diagnostic Tests

- Genetic testing is not routinely helpful.
- Neuroimaging may be useful for excluding other diagnoses.
- Medication history should be obtained to rule out drug-induced parkinsonism.

IPD develops insidiously and progressively worsens. Over many years, symptoms generally worsen to the point of severe disability, necessitating placement in a skilled nursing facility (especially with the development of dementia or frequent falling). However, in a subset of patients, clinical symptoms remain stable for many years.

Tremor of an upper extremity occurring at rest (and occasionally a postural tremor) is often the sole presenting complaint; however, only two-thirds of patients with IPD have tremor on diagnosis, and some never develop this sign. Tremor in IPD is present most commonly in the hands, sometimes with a characteristic pill-rolling motion. Less commonly, tremor may involve the jaw, legs, and toes. Like other motor features of IPD, resting tremor often begins unilaterally and becomes bilateral with disease progression. Stressful or emotional (either negative or positive) situations often increase the tremor amplitude and severity. Usually, volitional movement abolishes resting tremor, and tremor is absent during sleep. Although resting tremor is visibly noticeable in IPD and may cause social embarrassment for the patient, it often is the least physically disabling of the motor features.

Rigidity is the increased muscular resistance to passive range of motion and commonly affects the upper and lower extremities. If tremor is present in the affected extremity, the rigidity is associated with a cogwheel or ratchet-like quality upon examination. Facial muscles also are affected, resulting in hypomimia (masking of facial expressions) that may be erroneously interpreted as apathy, depression, or unfriendliness.

Bradykinesia refers to slowness of movement. Movement in IPD is often slow throughout an intended action, and difficulty with the

TABLE 68-1 Diagnostic Criteria for Idiopathic Parkinson's Disease and Differential Diagnosis

- Idiopathic Parkinson's disease
  - *Clinically possible:* Presence of one of the following: resting tremor, rigidity, or bradykinesia
  - *Clinically probable:* Presence of at least two of the following: resting tremor, rigidity, or bradykinesia
  - *Clinically definite:* Presence of at least two of the following: resting tremor, rigidity, or bradykinesia and a positive response to antiparkinsonian pharmacotherapy
- Differential diagonsis
- Essential tremor
- Secondary parkinsonism
  - Pharmacotoxicity (drug induced)
    - Antiemetics (e.g., metoclopramide, prochlorperazine)
    - Antipsychotics (e.g., phenothiazines, haloperidol, olanzapine, risperidone)
    - Other drugs (α-methyldopa, cinnarizine, flunarizine, tetrabenazine)
  - Environmental toxicity
    - Carbon monoxide poisoning
    - Manganese
    - Methanol

initiation of movement also occurs. A progressive slowing and decline in dexterity may impair tasks such as hand clapping, finger tapping, and handwriting (Fig. 68–3). Intermittent immobility (*freezing*) is another common characteristic. Freezing is especially likely to occur in situations such as when walking through a narrow doorway or initiating a turn. Patients also may experience a slow shuffling gait with difficulty halting their steps while in motion (festinating gait).

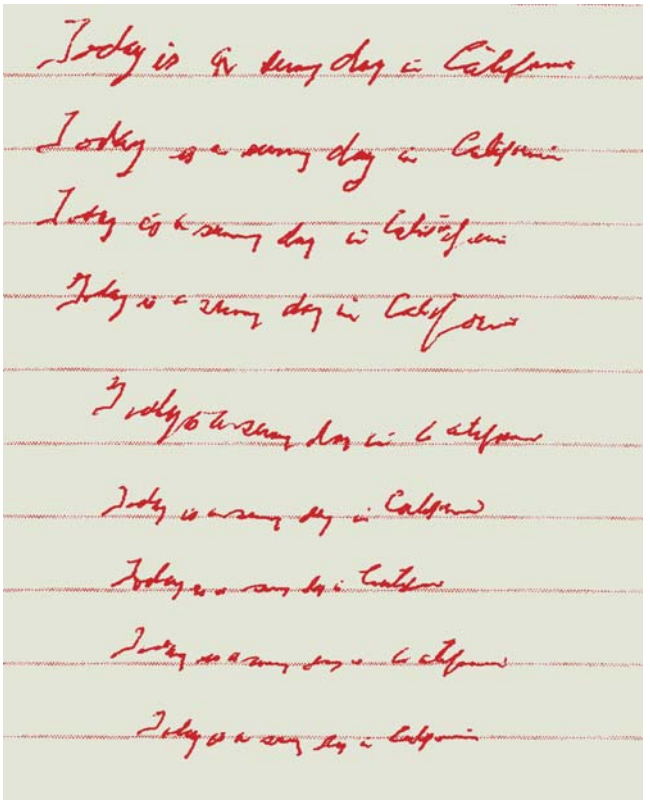

FIGURE 68-3. Example of micrographia in a patient with IPD. As the sentence, "Today is a sunny day in California" is repeatedly handwritten, progressive diminution of letter size occurs (micrographia). The height of each lined row is approximately 5/16 inches (8 mm). *(Courtesy of Jack J. Chen, PharmD, and David M. Swope, MD.)*

Postural instability, most common in advanced stages of IPD, is one of the most disabling problems of IPD because it increases the fall risk and is least amenable to pharmacotherapy. Testing for impaired postural responses by means of the pull test (in which a patient is unable to recover balance after sudden backward displacement at the shoulders) can help to identify the risk for falling. Many patients with impaired postural responses also have tendencies for propulsive gait (festination) and freezing, which also increases the risk of falling.

Although IPD is known predominantly as a disorder of motor capabilities, neuropsychiatric abnormalities also develop. Intellectual deterioration is not inevitable in IPD; however, some patients deteriorate in a manner indistinguishable from Alzheimer disease and other dementing conditions.[20] IPD patients are also at increased risk for anxiety and depression.[21] Although the disabilities of IPD may provoke depression in some instances, the underlying biochemical changes in the brain associated with IPD pathophysiology also predisposes for endogenous depression.

TREATMENT

DESIRED OUTCOMES

The goal in the management of IPD is to improve motor and nonmotor symptoms so that patients are able to maintain the best possible quality of life.[22] Specific objectives to consider when selecting an intervention include preservation of the ability to perform activities of daily living; improvement of mobility; minimization of adverse effects, treatment complications, putative disease modification; and improvement of nonmotor features such as

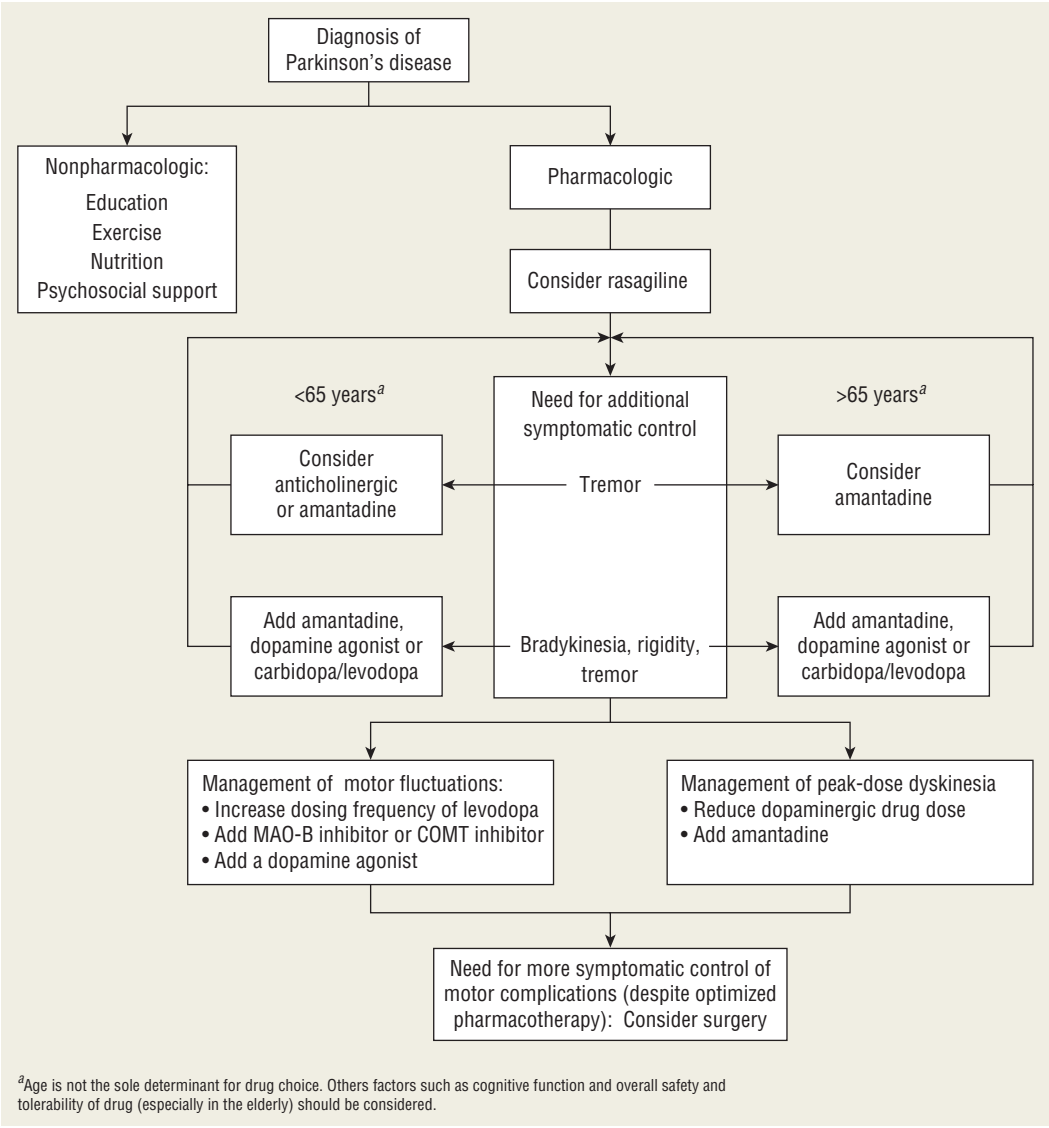

FIGURE 68-4. General approach to the management of early to advanced Parkinson's disease.

cognitive impairment, depression, fatigue, and sleep disorders. To accomplish some of these objectives, consultation with a specialist is helpful (e.g., movement disorders, physical therapy, psychiatry, and sleep medicine).

GENERAL APPROACH TO TREATMENT

1 Once a correct diagnosis of IPD is made, nonpharmacologic and pharmacologic interventions must be considered. Figure 68–4 illustrates a general treatment approach for early and advanced IPD and Table 68–2 summarizes antiparkinsonian medications and mechanisms of action. Treatment guidelines and monographs are updated frequently to keep up with new information and changes in treatment paradigms.[23–28]

2 In the absence of functional impairment, initial monotherapy may be initiated with an MAO-B inhibitor, such as rasagiline, with the addition of other therapeutic agents as IPD motor symptoms progressively worsen. Therapy with rasagiline in early stage PD has been demonstrated to slow the decline of motor function and is well tolerated. The definition of functional impairment is highly patient specific. Factors such as comorbid conditions, cognitive status, employment, lifestyle, and patients' desires must be considered when initiating pharmacotherapy. In a "physiologically" young patient experiencing functional impairment, monotherapy with a dopamine agonist or rasagiline is preferred. For patients who are older, cognitively impaired, or experiencing moderately severe functional impairment, L-dopa (e.g., carbidopa/levodopa) is preferred. Ultimately, all patients will require the use of L-dopa (either as monotherapy or in combination with other agents). With the development of motor fluctuations, addition of a catechol-*O*-methyltransferase (COMT) inhibitor should be considered to extend L-dopa duration of activity, or if the patient is not already on an MAO-B inhibitor or dopamine agonist, addition of either one should be considered. For management of L-dopa induced peak-dose dyskinesias, the addition of amantadine should be considered. Surgery is considered only in patients who need more symptomatic control or who are experiencing severe motor complications despite pharmacologically optimized therapy.

The treatment plan evolves as the disease progresses and must include consideration of short-term symptomatic relief as well as long-term effects. Patient specific factors that guide selection of therapies include the "functional" age of the patient, patient's desired outcomes, cognitive status, severity of motor features, and response to any previous IPD therapies. Patient education should be communicated with realistic optimism. For example, it

TABLE 68-2 Drugs Used in Parkinson's Disease[a]

Generic Name	Trade Name	Dosage Range[b] (mg/day)	Dosage Forms (mg)
Anticholinergic drugs			
Benztropine	Cogentin	0.5–4	0.5, 1, 2
Trihexyphenidyl	Artane	1–6	2, 5, 2/5mL
Carbidopa/levodopa products			
Carbidopa/L-dopa	Sinemet	300–1,000[c]	10/100, 25/100, 25/250
Carbidopa/L-dopa ODT	Parcopa	300–1,000[c]	10/100, 25/100, 25/250
Carbidopa/L-dopa CR	Sinemet CR	400–1,000[c]	25/100, 50/200
Carbidopa/L-dopa/entacapone	Stalevo	600–1,600[d]	12.5/50/200, 18.75/75/200, 25/100/200, 31.25/125/200, 37.5/150/200, 50/200/200
Carbidopa	Lodosyn	25–75	25
Dopamine agonists			
Apomorphine	Apokyn	3–12	30/3 mL
Bromocriptine	Parlodel	15–40	2.5, 5
Pramipexole	Mirapex	1.5–4.5	0.125, 0.25, 0.5, 1, 1.5
Pramipexole ER	Mirapex ER	1.5–4.5	0.375, 0.75, 1.5, 3, 4.5
Ropinirole	Requip	9–24	0.25, 0.5; 1, 2, 3, 4, 5
Ropinirole XL	Requip XL	8–24	2, 4, 6, 8, 12
COMT inhibitors			
Entacapone	Comtan	200–1,600	200
Tolcapone	Tasmar	300–600	100, 200
MAO-B inhibitors			
Rasagiline	Azilect	0.5–1	0.5, 1
Selegiline	Eldepryl	5–10	5
Selegiline ODT	Zelapar	1.25–2.5	1.25, 2.5
Miscellaneous			
Amantadine	Symmetrel	200–300	100, 50/5 mL

COMT, catechol-*O*-methyltransferase; CR, controlled release; MAO, monoamine oxidase; ODT, orally disintegrating tablet.
[a]Marketed in the United States for idiopathic Parkinson's disease.

should be explained that although there is no cure for IPD, modern medicine has many medications that can provide relief of symptoms. Nonpharmacologic interventions such as exercise should be encouraged, and attention to nonmotor features of IPD should not be neglected.

PHARMACOLOGIC THERAPY

Anticholinergic Medications

3 Because dopamine provides negative feedback to acetylcholine neurons in the striatum, the degeneration of nigrostriatal dopamine neurons also results in a relative increase of striatal cholinergic interneuron activity. This increased cholinergic activity (caused by dopamine depletion) is believed to contribute to the tremor of IPD. The anticholinergic drugs (e.g., benztropine and trihexyphenidyl) are considered effective against tremor but no more so than dopaminergic agents.[23–25] Sometimes dystonic symptoms associated with IPD are also improved by anticholinergic agents. Use of anticholinergic agents is limited due to the development of intolerable side effects, necessitating dosage reduction or drug discontinuation. Common adverse effects include blurred vision, confusion, constipation, dry mouth, memory difficulty, sedation, and urinary retention. Younger patients are better able to tolerate anticholinergic side effects, whereas patients with preexisting cognitive deficits and advanced age are less tolerant. Anticholinergic drugs can be used alone or in conjunction with L-dopa and other antiparkinson agents.

Amantadine

4 Amantadine provides modest symptomatic benefit for tremor, as well as rigidity and bradykinesia. The precise mechanism of action of amantadine is unknown, but dopaminergic and nondopaminergic mechanisms, such as inhibition of glutamatergic *N*-methyl-D-aspartate (NMDA) receptors, are implicated. Amantadine is typically administered 300 mg/day in divided doses. Amantadine is also useful for suppressing L-dopa–induced dyskinesia.[27] The antidyskinetic properties of amantadine are presumed to be mediated by antiglutamate activity which, in the setting of dyskinesias, appears to dominate over dopaminergic activity. Amantadine is eliminated renally, and a reduced dose should be administered when renal dysfunction is present (100 mg/day with creatinine clearances of 30–50 mL/min (0.50 to 0.84 mL/s), 100 mg every other day for creatinine clearances of 15–29 mL/min (0.25 to 0.49 mL/s), and 200 mg every 7 days for creatinine clearances of less than 15 mL/min (0.25 mL/s), and patients on hemodialysis).

Common side effects of amantadine include confusion, dizziness, dry mouth, and hallucinations. The elderly are particularly prone to develop confusion. Not uncommonly, amantadine may cause livedo reticularis, a reversible condition characterized by diffuse mottling of the skin affecting the upper or lower extremities and often accompanied by lower-extremity edema.

Carbidopa/L-Dopa

5 L-Dopa is the immediate precursor of dopamine and, in combination with a peripherally acting L-amino acid decarboxylase inhibitor (carbidopa or benserazide), remains the most effective drug for the symptomatic treatment of IPD.[23–25] L-Dopa crosses the blood–brain barrier, whereas dopamine, carbidopa, and benserazide do not. The combination of L-dopa with carbidopa or benserazide, reduces the unwanted peripheral conversion of L-dopa to dopamine. As a result, increased amounts of L-dopa are transported into the brain, and peripheral adverse effects of dopamine, such as nausea, are reduced. In the SNc, L-dopa is converted, via decarboxylation, to dopamine by the enzyme L-amino acid decarboxylase (Fig. 68–5). The converted dopamine is stored in the presynaptic SNc neurons until stimulated to be released into the synaptic cleft whereupon it binds to the D_1 and D_2 postsynaptic receptors. Dopamine activity is terminated primarily by reuptake back into the presynaptic neuron by means of a dopamine transporter. The enzymes MAO and COMT also inactivate dopamine.

5 Regardless of what the initial therapeutic agent is, ultimately all patients with IPD will require L-dopa at some point. An initial maintenance L-dopa regimen of 300 mg/day (in divided doses and in combination with carbidopa or benserazide) often is adequate. With regard to carbidopa, about 75 mg/day is required to sufficiently inhibit the peripheral activity of L-amino acid decarboxylase, but some patients require more. Therefore, the usual initial maintenance carbidopa/L-dopa regimen is 25/100 mg 3 times daily. As the motor features of IPD become progressively more severe, use of higher dosages is required. There is no maximum allowable total daily L-dopa dose; however, the usual maximal dose needed by patients, even those with severe IPD, is 800 to 1,000 mg/day. Slow buildup of dose (e.g., increments of 100 mg L-dopa per week) can help to minimize treatment emergent side effects, such as nausea, postural hypotension, sedation, vivid dreaming, and vomiting.

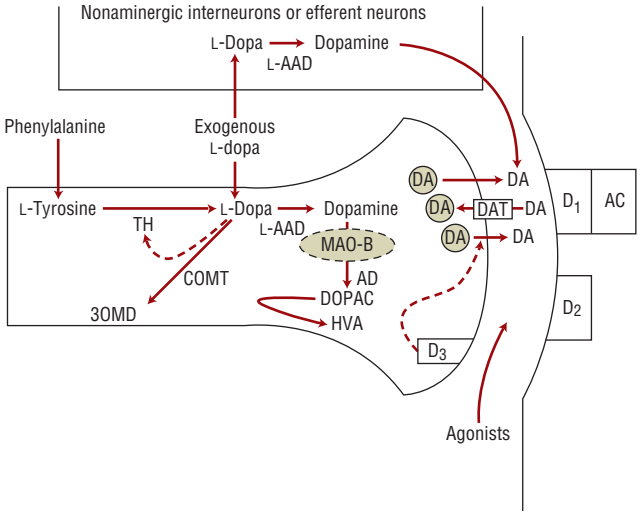

FIGURE 68-5. Dopamine metabolism in presynaptic dopamine neuron. (3OMD, 3-*O*-methyldopa; AC, adenylate cyclase; AD, aldehyde dehydrogenase; COMT, catechol-*O*-methyl transferase; D_1–D_3, dopamine receptors; DA, dopamine; DAT, dopamine transporter; DOPAC, 3,4-dihydroxyphenylacetic acid; HVA, homovanillic acid; L-AAD, L-aromatic amino acid decarboxylase; MAO-B, monoamine oxidase B; TH, tyrosine hydroxylase.)

For patients with difficulty swallowing tablets, an orally disintegrating tablet preparation of carbidopa/L-dopa is available. Although this formulation rapidly dissolves on contact with saliva, the carbidopa/L-dopa does not undergo transmucosal absorption and must reach the proximal duodenum for absorption.

Pharmacokinetics There is marked intra- and intersubject variability in the time to peak plasma concentrations after oral L-dopa, and this may in part be attributed to differences in gastric emptying. L-Dopa is absorbed primarily in the proximal duodenum by a saturable large neutral amino acid transport system. Competition for this transporter by dietary or supplemental large neutral amino acids (e.g., leucine, phenylalanine) can interfere with L-dopa bioavailability.

L-Dopa is not bound to plasma proteins. Active transport across the blood–brain barrier occurs by the large neutral amino acid transporter system. Because large amounts of dietary large neutral amino acids may compete for transport across the blood–brain barrier and interfere with the clinical response to L-dopa, separation of L-dopa administration with high protein meals has been recommended. However, in patients with early IPD, this interaction is generally not significant. In advanced IPD, special diets involving protein restriction or redistribution may improve L-dopa responsiveness and are sometimes implemented. A metabolite of L-dopa, 3-*O*-methyldopa, also competes for transport, but it is not clear how this affects L-dopa clinical response.

When peripheral decarboxylation of L-dopa is inhibited by carbidopa or benserazide, 3-*O*-methylation (via COMT) becomes the predominant catabolic pathway. The elimination half-life of L-dopa is about 1 hour, and this is extended to about 1.5 hours with the addition of carbidopa or benserazide. With the addition of a COMT inhibitor such as entacapone to carbidopa/L-dopa, the elimination half-life is extended to about 2 to 2.5 hours.

6 Motor Complications of L-Dopa Long-term L-dopa therapy is associated with a variety of motor complications, of which end-of-dose "wearing off" (motor fluctuations) and L-dopa peak-dose dyskinesias are the two most commonly encountered.[29] These motor complications can be disabling and challenging to manage. The approximate risk of developing either motor fluctuations or dyskinesia is 10% per year of L-dopa therapy.[30,31] However, motor complications can occur as early as 5 to 6 months after starting L-dopa therapy, especially if excessive doses are used initially.[32] Table 68–3 lists the motor complications associated with long-term treatment with L-dopa and suggested initial management strategies. Initiating therapy with the controlled-release form of carbidopa/L-dopa does not reduce the development of motor complications compared with standard-release carbidopa/L-dopa.[27]

TABLE 68-3 Common Motor Complications and Possible Initial Treatments

Effect	Possible Treatments
End-of-dose "wearing off" (motor fluctuation)	Increase frequency of carbidopa/L-dopa doses; add either COMT inhibitor or MAO-B inhibitor or dopamine agonist
"Delayed on" or "no on" response	Give carbidopa/L-dopa on empty stomach; use carbidopa/L-dopa ODT; avoid carbidopa/L-dopa CR; use apomorphine subcutaneous
Start hesitation ("freezing")	Increase carbidopa/L-dopa dose; add a dopamine agonist or MAO-B inhibitor; utilize physical therapy along with assistive walking devices or sensory cues (e.g., rhythmic commands, stepping over objects)
Peak-dose dyskinesia	Provide smaller doses of carbidopa/L-dopa; add amantadine

COMT, catechol-*O*-methyltransferase; CR, controlled release; MAO, monoamine oxidase; ODT, orally disintegrating tablet.

6 *End-of-Dose Wearing Off.* The terms "off" and "on" refer to periods of poor movement (i.e., return of tremor, rigidity, or slowness) and good movement, respectively. End-of-dose wearing off prior to a dose of medication is a common type of response fluctuation. This phenomenon is related to the increasing loss of neuronal storage capability for dopamine as well as the short half-life of L-dopa. Initially, exogenous L-dopa is taken up by the remaining SNc neurons, converted to dopamine, and stored in synaptic vesicles. With progressive loss of SNc neurons, storage capacity, and synthesis of endogenously derived dopamine, patients become more dependent on exogenous L-dopa. Hence the peripheral pharmacokinetic properties of L-dopa increasingly become the determinant of central dopamine synthesis. With advancing IPD, the duration of action of a single carbidopa/L-dopa dose progressively shortens, and in some cases may produce benefits for as little as 1 hour. As a result, carbidopa/L-dopa needs to be given more frequently so as to minimize daytime off episodes and to maximize on time. In addition to administering L-dopa doses more frequently, other options are available (see Table 68–3). In particular, the addition of the COMT inhibitor entacapone or the MAO-B inhibitor rasagiline extends the action of L-dopa, and either should be considered.[27] A controlled-release (CR) L-dopa product is available, but is not considered very effective for management of motor fluctuations.[27]

A dopamine agonist (e.g., pramipexole, ropinirole) also can be added to a carbidopa/L-dopa regimen in an attempt to minimize the occurrence of wearing off. For acute off episodes, a subcutaneously administered short-acting dopamine agonist, apomorphine, is available and possesses a rapid onset of effect (within 20 minutes). It is administered as needed.[33] Alternatively, chronic subcutaneous apomorphine infusion (not yet available in the United States) provides stable and continuous systemic and central drug concentrations and improves motor fluctuations and dyskinesias. Long-term therapy is limited by injection site skin reactions.[34] In addition, intraduodenal/jejunal L-dopa infusions produce constant and smoother stimulation of striatal dopamine receptors and thus stabilize response fluctuations. An infusible duodenal carbidopa/L-dopa gel (not yet available in the United States) has been demonstrated

to be an effective and safe therapy, and, as with subcutaneous apomorphine infusion, would be considered a last-line pharmacologic therapy for patients with persistent, on/off fluctuations.[35] Although not commonly performed, sipping small amounts of carbidopa/L-dopa solution very frequently throughout the day is also a method for managing on/off fluctuations. A solution that is stable for 72 hours at room temperature can be prepared by adding 10 tablets of carbidopa/L-dopa 10/100 (or 25/100) mg and 2 g crystalline ascorbic acid to 1 L of water.[36]

Often, off episodes occur during the night, and patients will awaken in an off state (as a consequence of an overnight decline of drug levels). Bedtime administration of a dopamine agonist or a drug formulation that provides sustained drug levels overnight (e.g., carbidopa/L-dopa CR, ropinirole XL, pramipexole ER) can help reduce nocturnal off episodes and improve functioning upon awakening.

"Delayed-On" and "No-On" Response. "Delayed-on" or "no-on" (a delayed or absent onset of drug effect, respectively) responses to individual doses of carbidopa/L-dopa can be a result of delayed gastric emptying or decreased absorption in the duodenum. Chewing a tablet or crushing it and then drinking a full glass of water, or using the orally disintegrating tablet formulation on an empty stomach, can help mitigate effects of delayed gastric emptying. Additionally, subcutaneously administered apomorphine may be used as rescue therapy from delayed-on or no-on periods. A drug-free period ("drug holiday") has been investigated in an attempt to modify postsynaptic dopamine receptors and thus decrease unpredictable off states. Although not commonly performed because of discomfort (to the patient) and medical risks, when drug holidays are performed, it should be under close medical supervision.

Freezing. "Freezing," or a sudden, episodic inhibition of lower-extremity motor function, may occur and will interfere with ambulation and increase the risk of falls. Patients may report that their "feet suddenly feel stuck to the floor" during ambulation or that they have difficulty initiating steps (start hesitation) or turns (turn hesitation). Freezing often is exacerbated by anxiety or when perceived obstacles (e.g., doorways, turnstiles) are encountered. Although changes to the antiparkinson drug regimen may be attempted, improvements are unlikely. Physical therapy along with assistive walking devices and sensory cues are helpful.

Dyskinesias. Another complication of L-dopa therapy is "on" period dyskinesias (involuntary choreiform movements involving usually the neck, trunk, and lower/upper extremities). If patients report "shakiness," it is important to clarify if they are referring to tremor or dyskinesias. Dyskinesias usually are associated with peak striatal dopamine levels (peak-dose dyskinesia) and, simplistically, can be thought of as too much movement secondary to extension of the pharmacologic effect resulting in excessive striatal dopamine receptor stimulation. Less commonly, dyskinesias also can develop during the rise and fall of L-dopa effects (the dyskinesia–improvement–dyskinesia or diphasic pattern of response). In the case of peak-dose dyskinesias, use of lower individual doses of L-dopa is beneficial. With the lowering of the L-dopa dose, dyskinesias improve but at the cost of returning parkinsonian features, thereby necessitating an increase in dosage frequency or addition of another agent to counteract the effects of using a lower L-dopa dose. Glutamate overactivity may also be involved as suggested by the antidyskinesia effect of amantadine (NMDA receptor antagonist) and positive results of investigational studies of antiglutamate ligands in animal models.[37] For severe dyskinesias (despite pharmacologically optimized therapy), surgery should be considered.

"Off-Period" Dystonia. In IPD, dystonias (sustained muscle contractions) can occur and more commonly affect a distal lower extremity (e.g., clenching of toes or involuntary turning of a foot). Dystonias often occur in the early morning hours (as a result of waning drug levels) and improve with the first L-dopa dose of the day. Remedies for early morning dystonia include bedtime administration of a long acting dopamine agonist, sustained-release carbidopa/L-dopa, baclofen, or focal injections of botulinum toxin (for persistent focal dystonia).

CLINICAL CONTROVERSY

The question of when to initiate L-dopa therapy is a matter of debate. Generally, initial therapy with a non–L-dopa agent is often recommended for patients younger than 65 years of age. Proponents for initiating non–L-dopa agents first and then adding L-dopa at a later point, cite evidence suggesting that long-term L-dopa therapy is associated with an increased risk of motor complications that can be disabling and challenging to manage. Additionally, drugs such as rasagiline and dopamine agonists provide sufficient symptom control for mild to moderate IPD. The counterargument is that L-dopa is inexpensive, more effective, and the development of motor complications is an acceptable trade-off. Age alone should not be the major deciding factor, and ultimately, individualized considerations of a patient's disability should guide all interventions for IPD.

Monoamine Oxidase B Inhibitors

4 Two selective MAO-B inhibitors, rasagiline and selegiline, are available in the United States for management of IPD. The selective inhibition of MAO-B in the brain interferes with the degradation of dopamine and results in prolonged dopaminergic activity. Both drugs contain a propargylamine moiety, which is essential for conferring irreversible inhibition of MAO-B. At therapeutic doses, these agents preferentially and irreversibly inhibit MAO-B over MAO-A.

A common concern with use of these agents is the potential for interactions with drugs that possess serotonergic activity. Concomitant use of MAO-B inhibitors with meperidine and other selected opioid analgesics is contraindicated because of a small risk of serotonin syndrome. However, concomitant use of other agents that enhance serotonin levels (e.g., antidepressants) is not contraindicated and can be used concomitantly when clinically warranted.

4 7 Selegiline, also known as L-deprenyl, is marketed for extending L-dopa effects and is typically administered 5 mg twice daily. Selegiline is also available as an orally disintegrating tablet formulation administered 1.25 to 2.5 mg once daily. A transdermal formulation of selegiline is also available but is not indicated for IPD. As monotherapy in early IPD, conventional selegiline provides modest improvements in motor function.[23–25] In more advanced IPD, the adjunctive use of conventional selegiline can provide up to 1 hour of extended on time for patients with wearing off, although the data are inconsistent.[27] This inconsistent effect of conventional selegiline may be explained, in part, by poor and erratic bioavailability of the parent drug.

As an amphetamine pharmacophore, selegiline undergoes first-pass hepatic metabolism (predominantly via cytochrome P450 [CYP] 2B6 and 2C19) to end products of L-methamphetamine and L-amphetamine. Adverse effects of selegiline are minimal but can include insomnia (especially if administered at bedtime), hallucinations, and jitteriness. Selegiline also increases

the peak effects of L-dopa and can worsen preexisting dyskinesias or psychiatric symptoms such as delusions. With the selegiline orally disintegrating tablet formulation, first-pass hepatic metabolism is bypassed as a consequence of transmucosal absorption of the drug. Hence, bioavailability characteristics of the parent drug are improved and formation of amphetamine metabolites is reduced. Thus, the selegiline orally disintegrating tablet formulation may provide an improved response relative to conventional selegiline.

4 7 Rasagiline is a second-generation, irreversible, selective MAO-B inhibitor administered at 0.5 or 1 mg once daily.[38] Rasagiline is effective as monotherapy in early IPD and also as add-on therapy for managing motor fluctuations in advanced IPD. In a large, placebo-controlled, 18-month, delayed-start clinical trial, patients initiated on rasagiline monotherapy early in IPD had less functional decline than did patients whose treatment was delayed for 9 months.[39] This suggests that earlier initiation with rasagiline (even before the onset of functional impairment) is associated with better long-term outcomes. For the management of patients with motor fluctuations, the efficacy of rasagiline appears similar to that of entacapone, offering approximately 1 hour of extra on time during the day.[40] Consequently, when an adjunctive agent is required for managing motor fluctuations, rasagiline is considered a first-line agent (as is entacapone).[27] Overall, rasagiline is well tolerated with minimal gastrointestinal or neuropsychiatric side effects. Rasagiline is metabolized by hepatic CYP1A2 to aminoindan, which is inactive and devoid of amphetamine-like properties.[38]

MAO-B inhibitors with a propargylamine molecular scaffolding have been investigated for neuroprotective properties (clinically referred to as disease modification). These agents inhibit the oxidative deamination of dopamine, which generates hydrogen peroxide and, ultimately, oxyradicals capable of damaging nigrostriatal neurons (see Fig. 68–1). Because MAO-B inhibition diverts dopamine catabolism to an alternate route that does not generate peroxide, MAO-B inhibitor therapy may spare neurons from oxidative stress. Additionally, MAO-B inhibitors have demonstrated antiapoptotic properties in laboratory experiments, further suggesting the possibility of disease modification. Clinical studies to demonstrate disease modification with selegiline have yielded inconclusive results, perhaps contributed in part by selegiline amphetamine metabolites as well as inadequate study methodology. However, results with rasagiline 1 mg/day from clinical studies utilizing methodology (i.e., delayed start) to demonstrate disease modification have been positive.[39,41]

CLINICAL CONTROVERSY

Great interest and debate surround the putative disease modifying effects of the MAO-B inhibitors. To date, only rasagiline has been shown to slow the rate of progression of motor impairment in patients with early IPD. A large clinical study demonstrated that earlier initiation of rasagiline is associated with better outcomes as compared to delaying therapy, and this was attributed to a disease modifying effect (as opposed to a symptomatic effect). Whether this is a class effect of MAO-B inhibitors is not known. However, selegiline is metabolized to amphetamine derivatives which have been demonstrated to neutralize neuroprotective effects in various preclinical studies. In a clinical study of the dopamine agonist pramipexole in patients with early IPD, no benefit of earlier initiation over delayed initation was observed.

COMT Inhibitors

7 Two COMT inhibitors, entacapone and tolcapone, have been developed to extend the effects of L-dopa and are indicated for managing wearing off.[27] Both reduce the peripheral conversion of L-dopa to dopamine, thus enhancing central L-dopa bioavailability. Consequently, in the absence of L-dopa, they have no effect on IPD symptoms. For patients with wearing off, these agents can decrease off-time significantly by increasing the L-dopa area under the curve by approximately 35%.[42] COMT inhibition is considered more effective than controlled-release carbidopa/L-dopa in providing consistent extension of L-dopa effect.[27] A triple-combination product of carbidopa/L-dopa/entacapone offers convenience for some patients (i.e., fewer tablets to administer).

Tolcapone inhibits both peripheral and central COMT. Its use is limited by reports of fatal hepatotoxicity, such that strict monitoring of hepatic function, especially during the first 6 months of therapy, is required. Because of the hepatotoxicity risk, tolcapone is reserved for patients with fluctuations that are not responding to other therapies.

Entacapone has a shorter half-life than tolcapone, and 200 mg needs to be given with each dose of carbidopa/L-dopa up to a maximum of 8 times per day. In clinical trials, both tolcapone and entacapone increased total daily on time by about 1 to 2 hours.[43,44] Dopaminergic adverse effects may occur and generally are manageable by reduction of the carbidopa/L-dopa dosage. With both agents, brownish-orange urinary discoloration may occur. Also, delayed onset of diarrhea (weeks to months later) can occur in up to 5% of patients. Unlike tolcapone, entacapone is not associated with hepatotoxicity and, if an adjunctive agent is needed for managing motor fluctuations, entacapone is considered one of the first choices.[27]

Dopamine Agonists

Dopamine agonists fall into two pharmacologic subtypes: ergot-derived agonists (bromocriptine) and the nonergot agonists (pramipexole, ropinirole). The nonergot dopamine agonists are safer than the ergot-derived agonists[45] and are useful as monotherapy in mild-moderate IPD, and also as adjuncts to L-dopa therapy in patients with motor fluctuations.[23–25,27] The dopamine agonists reduce the frequency of off periods and may allow reductions in L-dopa dosage.

8 Investigations comparing initial monotherapy with either L-dopa or a dopamine agonist in patients with IPD have revealed a significantly reduced risk of developing motor complications associated with dopamine agonists than with L-dopa.[46,47] Younger patients are more likely to develop motor complications; consequently, dopamine agonists are preferred over L-dopa. Older patients are more likely to experience intolerable side effects (e.g., hallucinations, orthostatic hypotension) from the dopamine agonists; consequently, carbidopa/L-dopa is preferred, particularly if cognitive problems or dementia is present. In terms of disease-modifying effects, the clinical data with dopamine agonists are inconclusive.[48–50]

Common adverse effects of dopamine agonists include nausea, confusion, hallucinations, light-headedness, lower-extremity edema, postural hypotension, sedation, and vivid dreaming. Less common but serious adverse effects include compulsive behaviors (e.g., pathologic gambling or shopping, hypersexuality), psychosis, and sleep attacks (sudden, unexpected episodes of sleep). Hallucinations and delusion can be managed using a stepwise approach (Table 68–4) that often involves the use of an atypical antipsychotic medication, such as clozapine or quetiapine.[21] The addition of a dopamine agonist to L-dopa therapy also can increase the frequency and severity of L-dopa induced dyskinesias, especially in patients with preexisting dyskinesias.

TABLE 68-4 Stepwise Approach to Management of Drug-Induced Hallucinosis and Psychosis in Parkinson's Disease

1. General measures such as evaluating for electrolyte disturbance (especially hypercalcemia or hyponatremia), hypoxemia, or infection (especially encephalitis, sepsis, or urinary tract infection).
2. Simplify the antiparkinsonian regimen as much as possible by discontinuing or reducing the dosage of medications with the highest risk-to-benefit ratio first.[a]
   a. Discontinue anticholinergics, including other nonparkinsonian medications with anticholinergic activity such as antihistamines or tricyclic antidepressants.
   b. Taper and discontinue amantadine.
   c. Discontinue monoamine oxidase-B inhibitor.
   d. Taper and discontinue dopamine agonist.
   e. Consider reduction of L-dopa (especially evening doses) and discontinuation of catechol-*O*-methyltransferase inhibitors.
3. Consider atypical antipsychotic medication if disruptive hallucinosis or psychosis persists.
   a. Quetiapine 12.5–25 mg at bedtime; gradually increase by 25 mg each week if necessary, until hallucinosis or psychosis improved or
   b. Clozapine 12.5–50 mg at bedtime; gradually increase by 25 mg each week if necessary until hallucinosis or psychosis improved (requires frequent monitoring for leukopenia).

[a]If dosage reduction or medication discontinuation is either infeasible or undesirable, go to step 3.

Initiation of a dopaminergic agonist is best performed by slow titration to minimize side effects. Pramipexole is initiated at a dose of 0.125 mg 3 times a day and increased every 5 to 7 days, as tolerated, to a maximum of 1.5 mg 3 times a day. An extended-release pramipexole formulation is also available for once-daily administration. Immediate-release ropinirole is initiated at 0.25 mg 3 times a day and increased by 0.25 mg 3 times a day on a weekly basis to a maximum of 24 mg/day. A controlled-release ropinirole formulation for once-daily administration is available.

Pramipexole is renally excreted with an 8- to 12-hour half-life. The initial dosage must be adjusted in renal insufficiency (0.125 mg twice daily for creatinine clearances of 35 to 59 mL/min [0.58 to 0.99 mL/s], 0.125 mg once daily for creatinine clearances of 15 to 34 mL/min [0.25 to 0.57 mL/s]). Ropinirole has a 6-hour half-life and is metabolized by CYP1A2. Potent inhibitors (e.g., fluoroquinolone antibiotics) and inducers (e.g., cigarette smoking) of this enzyme likely will lead to alterations in ropinirole clearance.

Apomorphine is an injectable nonergot dopamine agonist. It is an aporphine alkaloid originally derived from morphine but lacks narcotic properties.[33] Because of extensive hepatic first-pass metabolism, apomorphine is not suitable for oral administration and is administered subcutaneously. In some countries, apomorphine is also available for continuous subcutaneous infusion with minipumps. Apomorphine should not be injected intravenously. For patients with advanced IPD who are experiencing intermittent off episodes despite optimized therapy, administration of subcutaneous apomorphine effectively triggers an "on" response within 20 minutes.[33] The effective dose ranges from 2 to 6 mg per injection, with most patients requiring approximately 0.06 mg/kg. Sites of injection (abdomen, upper arm, and upper thigh) should be rotated to avoid development of subcutaneous nodules. The metabolic pathway of apomorphine remains unknown. Apomorphine elimination half-life is approximately 40 minutes, and the duration of benefit can be up to 100 minutes. Nausea and vomiting are common side effects, and prior to the initiation of apomorphine, patients should be premedicated with the antiemetic trimethobenzamide. Other side effects include dizziness, hallucinations, injection-site irritation, orthostatic hypotension, somnolence, and yawning. As a consequence of reports of severe hypotension and syncope, apomorphine is contraindicated with drugs in the serotonin ($5HT_3$)-receptor blocker class, including dolasetron, granisetron, and ondansetron.

SURGICAL THERAPY

9 Currently, surgery should be considered as an adjunct to pharmacotherapy when patients are experiencing frequent motor fluctuations or disabling dyskinesia or tremor despite an optimized medical regimen. There are several patient-selection criteria for surgery, including a diagnosis of L-dopa–responsive IPD. Anatomic targets include the thalamus, GPi, and the subthalamic nucleus. Bilateral, chronic, high-frequency electrical stimulation of a target site, also known as deep-brain stimulation (DBS), is the preferred surgical modality.[51]

In DBS surgery, a battery-powered neurostimulator (pacemaker-like device) is implanted subcutaneously below the clavicle and provides constant electrical stimulation, via electrode wires, to the targeted brain structure. Thalamic DBS is very effective for suppressing tremor (specifically arm tremor), but it does not significantly improve the other parkinsonian features (bradykinesia, rigidity, motor fluctuations, or dyskinesias). Although debatable, subthalamic nucleus DBS is favored over GPi DBS because it is considered more effective. Subthalamic nucleus DBS is associated with improvements in tremor, rigidity, bradykinesia, motor fluctuations, and dyskinesia, as well as lowering of antiparkinsonian medications. Problems with gait and postural instability do not improve significantly with DBS (or pharmacotherapy) and remain an unmet need; however, preliminary results for DBS of the pedunculopontine nucleus appear promising.[52]

DBS procedures require routine adjustment of the electrical stimulation parameters (e.g., voltage, frequency, and pulse width) to achieve optimal control while minimizing side effects. The electrical stimulation parameters (or "electrical dosage") are adjusted via a programmable handheld device to meet each patient's needs and are performed by physicians as well as other trained individuals, including nurse practitioners and clinical pharmacists.

In recent years, cell-based restorative procedures have appeared promising (implantation of dopamine producing cells such as human fetal mesencephalon tissue or retinal pigmented epithelial cells into the striatum) but have yielded disappointing clinical results.[53–54] Gene-based therapies are currently under investigation and remain highly experimental.[55]

PHARMACOECONOMIC CONSIDERATIONS

Pharmacoeconomic assessments in IPD are important. IPD places a high economic burden on society.[56] Based on an estimated 1 million cases of IPD in the United States, the direct costs associated with IPD are in the range of $4 to $8 billion per year. If indirect costs, such as lost productivity, are included, the economic burden of IPD significantly increases. Patient-specific factors that influence the cost of IPD include age of symptom onset; level of disability; presence of motor complications, falls, and dementia; and need for skilled nursing. For cost-effectiveness, the lowest dose that provides satisfactory symptomatic results should be used and, for patients already on carbidopa/L-dopa, optimization of the L-dopa regimen should be attempted before adding adjunctive agents. As the severity and level of disability increase, so do the costs associated with IPD. Likewise, the costs of treating patients with motor complications are considerably more than the costs of treating patients without motor complications. A similar trend applies for patients with hallucinations and psychosis who incur greater costs associated with nursing home placement. In more advanced

TABLE 68-5 Monitoring Parkinson's Disease Therapy

1. Monitor medication administration times. Educate the patient that immediate-release carbidopa/L-dopa is absorbed best on an empty stomach but is commonly taken with food to minimize nausea. Avoid administration of conventional selegiline in the late afternoon or evening to minimize insomnia.
2. Monitor to ensure that the patient and/or caregivers understand the prescribed medication regimen. For example, catechol-*O*-methyltransferase inhibitors work by enhancing the effect of L-dopa and that the patient should not discontinue medication without notifying the clinician.
3. Monitor and inquire specifically about dose-by-dose effects of medication, including response to doses of medication and the presence of dyskinesias, wearing-off effects, dizziness, nausea, or visual hallucinations. Offer suggestions to help alleviate these or encourage the patient to discuss with them with the clinician.
4. Monitor and inquire about concerns that caregivers may have about the patient, such as presence of abnormal behaviors, dyskinesias, falls, hallucinations, memory problems, mood changes, and sleep disorders.
5. Monitor for nonadherence and, if present, inquire for possible reasons (e.g., dosing convenience, financial issues, adverse effects) and offer suggestions.
6. Monitor for presence of drugs that can exacerbate idiopathic Parkinson's disease motor features (e.g., D_2 receptor blockers) or if the presence of an anticholinergic agent is causing cognitive impairment.

stages, the continued use of a dopamine agonist, MAO-B inhibitor, or COMT inhibitor can be a considerable expense for the patient, and the benefits must outweigh the potential risks or side effects. Pharmacologic treatments that delay disability or reduce the development of motor complications should be considered cost-effective in the long run.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 68–5 lists the monitoring parameters for Parkinson's disease therapy. Patient and caregiver satisfaction is an important component of evaluating therapeutic outcomes. Toward this end, establishing appropriate treatment expectations is important and patients and caregivers should be educated that IPD is a neurodegenerative disease that progresses with time, and that some features will respond less well to pharmacotherapy (e.g., freezing, gait and postural instability). Patients and caregivers can participate in treatment by recording medication administration times as well as the duration of on and off times that can be reviewed at each visit. Periodic review of all medications that the patient is taking should be performed to identify use of medications (e.g., D_2-receptor blockers) that can exacerbate IPD motor features. If the patient reports memory problems, the medication profile should be screened for medications with anticholinergic properties and, if present, eliminated when possible. Assessment of the patient's general level of functioning, including activities of daily living and mobility, is important to determine when medication adjustments or physical therapy interventions are needed. Screening for anxiety or depressive disorders will help to determine if antidepressant or antianxiety therapy is needed. If falling is a problem, it is important to investigate whether falls are secondary to insufficient motor control or drug side effects such as dizziness and orthostatic hypotension. The former may necessitate an increase in dose of antiparkinson agents, and the latter a reduction in drug dosage. Physical therapy is also helpful for strengthening ambulation and balance skills to minimize falls. The patient should be questioned about any difficulties with their antiparkinson medications, including presence of adverse effects. Recommendations always should be made in view of the patient's perception of the severity of symptoms and effect on quality of life.

CONCLUSIONS

1 Despite many advances in neuroscience, a definitive cause of IPD remains unknown. Each of the available therapies provide various degrees of symptomatic benefit, and the choice of agent is patient specific. The appropriate pharmacotherapy can significantly improve a patient's quality of life and functional status. The goal of management remains maintaining acceptable functional control with minimal treatment emergent complications. Thoughtful consideration for choice of initial and adjunctive therapy is critical for optimizing short- and long-term outcomes.

ABBREVIATIONS

COMT: catechol-*O*-methyl-transferase

CR: controlled release

DBS: deep-brain stimulation

GABA: γ-aminobutyric acid

GPi: globus pallidus interna

IPD: idiopathic Parkinson's disease

L-dopa: levodopa

MAO: monoamine oxidase

MPP^+: 1-methyl-4-phenylpyridinium

MPTP: 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine

NMDA: *N*-methyl-D-aspartate

SNc: substantia nigra pars compacta

CHAPTER 69

Pain Management

TERRY J. BAUMANN, JENNIFER M. STRICKLAND, AND CHRIS M. HERNDON

KEY CONCEPTS

1. It is important, whenever possible, to ask patients if they have pain, to identify the source of pain, and to assess the characteristics of the pain.
2. Patients taking analgesics should be monitored for response and side effects, particularly sedation and constipation associated with the opioids.
3. Oral analgesics are preferred over other dosage forms whenever feasible, but it is important to adjust the route of administration to the needs of the patient.
4. Equianalgesic doses are useful as a guide when converting from one agent to another, but further dose titration usually is required to achieve treatment goals.
5. Doses must be individualized for each patient and administered for an adequate duration of time. Around-the-clock regimens should be considered for acute and chronic pain. As-needed regimens should be used for breakthrough pain or when acute pain displays wide variability and/or has subsided greatly.
6. For chronic pain that has a maladaptive inflammatory and/or neuropathic component, anticonvulsants, topical analgesics, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and opioids should be considered.
7. Whenever possible, a multidisciplinary approach and nonpharmacologic strategies should be used.
8. Placebo therapy should not be used as an attempt to diagnose psychogenic pain.

Although the world is full of suffering, it is also full of the overcoming of it.

Helen Keller[1]

Humans have always known and sought relief from pain.[2] Today, pain's impact on society still is great, and indeed pain complaints remain a primary reason patients seek medical advice.[3]

Regrettably, many healthcare providers do not receive adequate training in this area, and new information is not widely disseminated and/or understood. Clearly, pain management is enhanced when a multidisciplinary approach is applied. Thus, understanding the pathophysiology of pain therapy and maintaining a working knowledge of individual pain regimens are important key factors in addressing pain control.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

DEFINITION

The accepted current definition of pain is: "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[4] Pain often is so subjective, however, that many clinicians define pain as whatever the patient says it is. The best care is achieved when the patient comes first.

EPIDEMIOLOGY

Data from the National Health and Nutrition Examination Survey indicate that 1 in 4 Americans have suffered pain that lasts for more than 24 hours in the previous month and in those reporting pain, 42% state that it lasted more 1 year.[5] Seventy-six and a half million Americans report they are in chronic pain; this is more than the number of patients with heart disease, cancer, and diabetes combined.[6] The annual cost of pain to U.S. society can be estimated to be in the billions of dollars.[6,7] In 1 year, an estimated 25 million Americans will experience acute pain due to injury or surgery, and one-third of Americans will experience severe chronic pain at some point in their lives.[3] These numbers are expected to rise, as increasingly more Americans work beyond age 60 years and survive into their 80s.[7] The 106th Congress passed Title VI, Section 1603, of H.R. 3244 which declared a 10-year interval starting January 1, 2001, the "Decade of Pain Control and Research".[5] Unfortunately, despite much public attention, considerable focused education, and a number of consensus guidelines, pain often remains underestimated and undertreated.[3,5,8,9]

PATHOPHYSIOLOGY

The pathophysiology of pain involves a complex array of neural networks in the brain that are acted on by afferent stimuli to produce the experience we know as pain. In acute pain, this encounter is short lived; but in some situations, the changes may persist, and chronic pain develops.[10]

NOCICEPTIVE PAIN

Nociceptive pain typically is classified as either somatic (arising from skin, bone, joint, muscle, or connective tissue) or visceral

(arising from internal organs such as the large intestine or pancreas).[11] Whereas somatic pain often presents as throbbing and well localized, visceral pain can manifest as pain feeling as if it is coming from other structures (referred) or as a more localized phenomenon.[11] We can think of nociception in terms of stimulation, transmission, perception, and modulation.[11]

Stimulation

The first step leading to the sensation of pain is stimulation of free nerve endings known as *nociceptors*. These receptors are found in both somatic and visceral structures. They distinguish between noxious and innocuous stimuli, and they are activated and sensitized by mechanical, thermal, and chemical impulses.[11] The underlying mechanism of these noxious stimuli (which in and of themselves may sensitize/stimulate the receptor) may be the release of bradykinins, hydrogen and potassium ions, prostaglandins, histamine, interleukins, tumor necrosis factor alfa, serotonin, and substance P (among others) that sensitize and/or activate the nociceptors.[12] Receptor activation leads to action potentials that are transmitted along afferent nerve fibers to the spinal cord (Fig. 69–1).[11]

Transmission

Nociceptive transmission takes place in Aδ and C-afferent nerve fibers.[11] Stimulation of large-diameter, sparsely myelinated Aδ fibers evokes sharp, well-localized pain, whereas stimulation of unmyelinated, small-diameter C fibers produces dull, aching, poorly localized pain.[11]

These afferent, nociceptive pain fibers synapse in various layers (laminae) of the spinal cord's dorsal horn, releasing a variety of neurotransmitters, including glutamate, substance P, and aspartate.[13] The complex array of events that influence pain can be explained in part by the interactions between neuroreceptors and neurotransmitters that take place in this synapse. For example, by stimulating sensory myelinated fibers that intraconnect in the dorsal horn with pain fibers, nonnoxious stimuli can have an inhibitory effect on pain transmission (Fig. 69–1).[13] Functionally, the importance of the interplay between these different fibers and various neurotransmitters and neuroreceptors is evident in the analgesic response produced by topical irritants or transcutaneous electrical nerve stimulation. These pain-initiated processes reach the brain through a complex array of a number of ascending spinal cord pathways, which include the spinothalamic tract.[13] Information other than pain is also carried along these pathways. Thus, pain is influenced by many factors supplemental to nociception and precludes simple schematic representation. It is postulated that the thalamus acts as a relay station, as these pathways ascend and pass the impulses to central structures where pain can be processed further.[11]

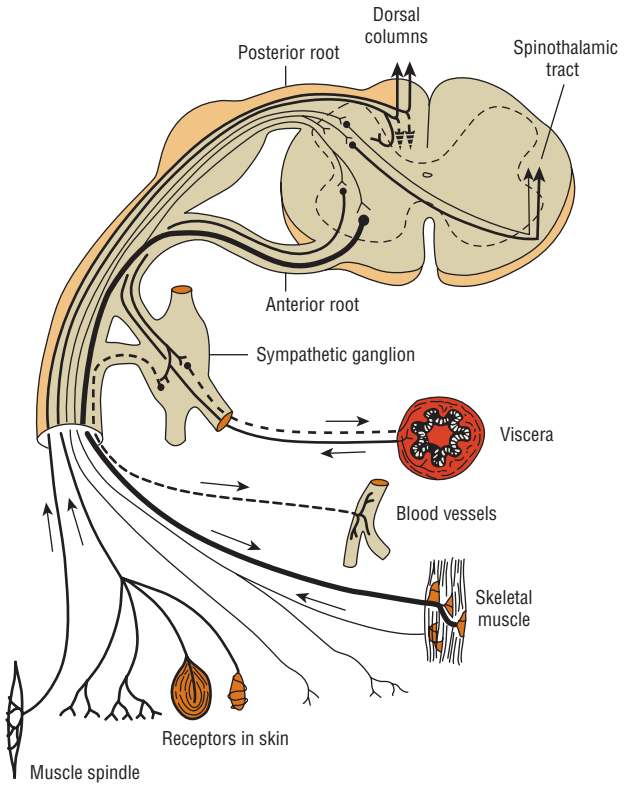

FIGURE 69-1. Schematic representation of nociceptive pain. *(Data modified from reference 69.)*

Pain Perception

At this point in transmission, pain is thought to become a conscious experience that takes place in higher cortical structures. The brain may accommodate only a limited number of pain signals, and cognitive and behavioral functions can modify pain. Relaxation, distraction, meditation, and guided mental imagery may decrease pain by limiting the number of processed pain signals.[11] In contrast, a change in our neurobiochemical makeup that results in states such as depression or anxiety may worsen pain.

Modulation

The body modulates pain through a number of complex processes. One, known as the *endogenous opiate system*, consists of neurotransmitters (e.g., enkephalins, dynorphins, and β-endorphins) and receptors (e.g., μ, δ, and κ) that are found throughout the central nervous system (CNS).[14] Like exogenous opioids, endogenous opioids bind to opioid receptor sites and modulate the transmission of pain impulses.[11] Other receptor types also can influence this system. Blockade of *N*-methyl-D-aspartate (NMDA) receptors, found in the dorsal horn, may increase the μ-receptors' responsiveness to opiates.[14]

The CNS also contains a highly organized descending system for control of pain transmission. This system can inhibit synaptic pain transmission at the dorsal horn and originates in the brain.[11] Important neurotransmitters here include endogenous opioids, serotonin, norepinephrine, and γ-aminobutyric acid (GABA).[11]

Adaptive Inflammation

Inflammatory pain can be thought of as the body's shifting from preventing tissue damage to the promotion of healing (e.g., surgical wounds, traumatic injury).[10] As a result of the inflammatory process, the pain threshold is reduced and the injured area becomes more sensitive to pain.[10] This process decreases our contact with and movement of the injured area, thus promoting the progression of healing.[10] When this course of action outlives its functionality or when it is caused by diseases such as arthritis, it can move from an acute to a chronic problem (maladaptive inflammation).[10] According to McPherson[15]: "In response to tissue damage and inflammation, a significant alteration occurs in the chemical composition and properties of the neurons that innervate the inflamed tissues. These alterations reflect the nature and levels of the different proteins expressed by the sensory neurons. Altered production of these proteins may modify the phenotypes of the neurons, changing their transduction and transmission properties. Inflammatory pain is also associated with an increase in the excitability or responsiveness of neurons within the CNS, referred to as *central sensitization.* This phenomenon, like peripheral sensitization, is a major cause of hypersensitivity to pain after injury."

NEUROPATHIC AND FUNCTIONAL PAIN

Neuropathic and functional pain is distinctly different from nociceptive pain in that it becomes disengaged from noxious stimuli or healing[10] and often is described in terms of chronic pain. Neuropathic pain is a result of nerve damage, whereas functional pain can be thought of as abnormal operation of the nervous system.[10] A number of neuropathic pain syndromes (e.g., postherpetic neuralgia, diabetic neuropathy) and functional pain syndromes (e.g., fibromyalgia, irritable bowel syndrome, sympathetic induced pain, tension-type headaches, and some noncardiac chest pain)[10] exist. They often are underrecognized and difficult to treat.[11] In addition, the pain reported often is not evident by examining physical findings.[11]

The mechanism responsible for neuropathic and functional pain may be the nervous system's endogenous dynamic nature. Nerve damage or certain disease states may evoke changes seen in inflammatory pain, ectopic excitability, enhanced sensory transmission, nerve structure reorganization, and loss of modulatory pain inhibition.[10,15] Pain circuits rewire themselves both anatomically and biochemically.[16] This produces a mismatch between pain stimulation and inhibition, and a potential progressive increase in the discharge of dorsal horn neurons.[16]

Clinically, patients present with episodic or continuous pain transmission (often described as burning, tingling, shock like, or shooting), exaggerated painful response to normally noxious stimuli (hyperalgesia), and/or painful response to normally nonnoxious stimuli (allodynia).[3,16] This change over time may help to explain why this type of pain often manifests long after the actual nerve-related injury or when no actual injury is identified.

CLASSIFICATION OF PAIN

It is helpful in understanding pain to subdivide the presenting symptoms into acute pain, chronic pain, and cancer pain.

ACUTE PAIN

Acute pain can be a useful physiologic process, warning individuals of disease states and potentially harmful situations. Unfortunately, severe, unremitting, undertreated acute pain, when it outlives its biologic usefulness, can produce many deleterious effects. Aside from unnecessary suffering, untreated and undertreated acute pain has also been shown to increase one's risk for the development of chronic pain syndromes.[17] Acute pain is usually nociceptive in nature with common causes, including surgery, acute illness, trauma, labor, and medical procedures.[3]

CHRONIC PAIN

Under normal conditions, acute pain subsides quickly as the healing process decreases the pain-producing stimuli; however, in some instances, pain persists for months to years, leading to a chronic pain state with features quite different from those of acute pain (Table 69–1). This type of pain can be nociceptive, neuropathic/functional, or mixed.[3] Chronic pain can be classified as either being associated with cancer (cancer pain) or from noncancer etiologies (chronic noncancer pain). Chronic pain may result in changes to the receptors and nerve fibers in the nervous system, often making treatment even more difficult.[18]

CANCER PAIN

Pain associated with potentially life-threatening conditions is often called malignant pain or simply cancer pain.[3] This type of pain includes both chronic and acute components and often has multiple etiologies. It is pain caused by the disease itself (e.g., tumor invasion, organ obstruction), treatment (e.g., chemotherapy, radiation, surgical incisions), or diagnostic procedures (e.g., biopsy).[3]

TABLE 69-1 Characteristics of Acute and Chronic Pain

Characteristic	Acute Pain	Chronic Pain
Relief of pain	Highly desirable	Highly desirable
Dependence and tolerance to medication	Unusual	Common
Psychological component	Usually not present	Often a major problem
Organic cause	Common	May not be present
Environmental/family issues	Small	Significant
Insomnia	Unusual	Common component
Treatment goal	Cure	Functionality
Depression	Uncommon	Common

Data from Stimmel[2] and Jacobson and Mariano.[60]

CLINICAL PRESENTATION

A patient-oriented approach is essential, and evaluation methods should not differ from those used in other medical conditions.[2] 1 Therefore, a comprehensive history and physical examination are imperative to evaluate underlying diseases and possible other contributing factors.[2] This includes asking if the patient has pain and identifying the source of pain when possible, however, the absence of a discreet etiology should not preclude pain treatment.[2] A baseline characterization of pain can be obtained by assessing characteristics outlined in Table 69–2.[19]

Numerous validated scoring tools exist (e.g., numeric rating scale, visual analog scale, etc.),[3,20-22] however the tools need to be appropriate for the type of pain being evaluated, and can be inadequate if not used consistently, or used without clinical judgment. 2 Proper patient assessment must include an evaluation of pain management. Pain intensity, pain relief, and medication side effects (e.g., opioid-induced sedation or constipation) must be assessed and reassessed on a regular basis. The timing and regularity of this assessment will depend on the type of pain and the medications administered. Postoperative pain and acute exacerbation of cancer pain may need to be assessed hourly, whereas chronic noncancer pain may require only daily or less frequent assessment. Pain intensity assessment is vital in acute pain, whereas functionality becomes more of an issue in chronic pain. Quality of life must be assessed on a regular basis in all patients. Many advocate using the four "A"s (analgesia, activity, aberrant drug behavior, and adverse effects) as key assessment measures for any patient with chronic pain.[23]

TABLE 69-2 Characteristics of Pain

Onset and duration	When did pain begin and how long has it been since the pain began?
Palliative factors	What makes the pain better?
Provocative factors	What makes the pain worse?
Quality	Describe the pain.
Location	Where is the pain?
Severity/intensity	How does this pain compare with other pain you have experienced?
Temporal factors	Does the intensity of the pain change with time?

Data from Twycross[19] and Berry et al.[3]

It is important to note that often objective signs are lacking for pain evaluation. Acute pain may result in increased sympathetic tone (e.g., hypertension, tachycardia, tachypnea); however, this response is usually diminished as acute pain progresses to chronic pain. The clinician must rely on the patient's description of their pain.[24]

CLINICAL PRESENTATION OF PAIN

Acute

General

- Obvious distress (e.g., trauma), infants may present with changes in feeding habits, increased fussiness. Those with dementia may exhibit changes in eating habits, increased agitation, calling out. Attention also must be given to mental/emotional factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear in particular, are noted to lower this threshold, whereas rest, mood elevation, sympathy, diversion, and understanding raise the pain threshold.

Symptoms

- Can be described as sharp, dull, shock like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these occur in a timely relationship with an obvious noxious stimuli).

Signs

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor, but these signs are *not diagnostic.*
- In some cases there are no obvious signs.
- Comorbid conditions usually not present.
- Outcome of treatment generally predictable.

Laboratory Tests

- Pain is always subjective.
- There are *no* specific laboratory tests for pain.
- Pain is best diagnosed based on patient description and history.

Chronic

General

- Can appear to have no noticeable suffering. Attention also must be given to mental/emotional factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear in particular, are noted to lower this threshold; whereas rest, mood elevation, sympathy, diversion, and understanding raise the pain threshold.

Symptoms

- Can be described as sharp, dull, shock-like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these often occur *without* a timely relationship with an obvious noxious stimuli).
- Over time, the pain stimulus may cause symptoms that completely change (e.g., sharp to dull, obvious to vague).

Signs

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor are seldom present.
- In most cases there are *no* obvious signs.
- Comorbid conditions often present (e.g., insomnia, depression, anxiety).
- Outcome of treatment often unpredictable.

Laboratory Tests

- Pain is always subjective.
- Pain is best diagnosed based on patient description and history.
- There are *no* specific laboratory tests for pain; however, history and/or diagnostic proof of past trauma (e.g., computed tomography) or present disease state (e.g., auto-antibodies) may be helpful in diagnosing etiology. General labs that may be considered include vitamin D levels, thyroid stimulating antibodies, and B_{12}.

Data from Twycross,[19] American Pain Society,[24] Turner et al.,[57] Hagen et al.,[58] Bernard et al.[59]

TREATMENT

NONPHARMACOLOGIC THERAPY

Various nonpharmacologic therapies have been found to be beneficial in the management of acute and chronic pain, including physical manipulation, application of heat or cold, massage, and exercise.[25]

Transcutaneous electrical nerve stimulation (TENS) has been used in managing both acute and chronic pain (e.g., surgical, traumatic, neuropathy, and musculoskeletal pain).[3] However, published evidence regarding long-term benefit is limited. As a result, routine use has not gained widespread acceptance.

Even though the cognitive, behavioral, and social aspects of pain are well established, psychological interventions for the treatment of acute pain are not used widely. Simple interventions (e.g., education or introductory information about sensations to expect after certain procedures) reduce patient distress and greatly reduce postprocedure suffering.[26] Other successful psychological techniques, including relaxation training, imagery, and hypnosis, have proven effective in the management of postprocedure pain and in cancer-related pain.[26,27] Moderate evidence demonstrates that cognitive behavioral therapy and biofeedback also may be useful nonpharmacologic tools in managing chronic pain.[28]

PHARMACOLOGIC TREATMENT

Many consider pharmacologic treatment to be the cornerstone of pain management.

Nonopioid Agents

Analgesia should be initiated with the most effective analgesic agent having the fewest side effects. Acetaminophen, acetylsalicylic acid (aspirin), and nonsteroidal antiinflammatory drugs (NSAIDs) often are preferred over opiates in the treatment of mild-to-moderate pain (Table 69–3). These drugs (with the exception of acetaminophen) prevent formation of prostaglandins produced in response to noxious stimuli, thereby decreasing the number of pain impulses received by the CNS.[24] NSAIDs may be particularly useful in the management of cancer-related bone pain.[27] Studies comparing the efficacy of these agents have been inconsistent. Therefore, the choice of a particular agent often depends on availability, cost, pharmacokinetics, pharmacologic characteristics, and the side-effect profile. Because of the large interpatient variability in response to individual NSAIDS, it is considered rational therapy to switch to another member of this class if there is inadequate response after a sufficient therapeutic trial of any single agent.[24] The duration of a sufficient trial has not been well defined; however, typically, a NSAID should be continued for a minimum of 1 month prior to evaluating the need to switch agents.

TABLE 69-3 Adult FDA-Approved Nonopioid Analgesics (Includes Only FDA-Approved Agents for Pain)

Class and Generic Name (Brand Name)	Approximate Half-Life (h)	Usual Dosage Range (mg)	Maximal Dose (mg/day)
Salicylates			
Acetylsalicylic acid[a]–aspirin (various)	0.25	325–1,000 every 4–6 h	4,000
Choline and magnesium trisalicylate (various)	9–17	1,000–1,500 every 12 h 750 every 8 h (elderly)	3,000
Diflunisal (Dolobid, various)	8–12	500–1,000 initial 250–500 every 8–12 h	1,500
Salsalate (various)	1	1,000 every 12 h or 500 every 6 hours	3,000
Para-aminophenol			
Acetaminophen[a] (Tylenol, various)	2–3	325–1,000 every 4–6 h	4,000[b]
Fenamates			
Meclofenamate (various)	0.8–3.3	50–100 every 4–6 h	400
Mefenamic acid (Ponstel)	2	Initial 500 250 every 6 h (max. 7 days)	1,000[c]
Pyranocarboxylic acid			
Etodolac (various) (immediate release)	7.3	200–400 every 6–8 h	1,000 1,200 with extended-release product
Acetic acid			
Diclofenac potassium [Cataflam, various, Flector (patch)]	1.9	In some patients, initial 100, 50 three times per day Patch available–to be applied twice daily to painful area (intact skin only)	150[d]
Propionic acids			
Ibuprofen[a] (Motrin, Caldolor, various)	2–2.5	200–400 every 4–6 h Injectable, 400–800 every 6 h (infused over 30 min)	3,200[e] 2,400[e] 1,200[f]
Fenoprofen (Nalfon, various)	3	200 every 4–6 h	3,200
Ketoprofen (various)	2	25–50 every 6–8 h	300 200 with extended-release product
Naproxen (Naprosyn, Anaprox, various)	12–17	500 initial 500 every 12 h or 250 every 6–8 h	1,000[c]
Naproxen sodium[a] (Aleve, various)	12–17	In some patients, 440 initial[f] 220 every 8–12 h[f]	660[f]
Pyrrolizine carboxylic acid			
Ketorolac–parenteral (various)	5–6	30[g]–60 (single IM dose only) 15[g]–30 (single IV dose only) 15[g]–30 every 6 h (IV dose) (max. 5 days)	30[g] –60 15[g]–30 60[g]–120
Ketorolac–oral, indicated for continuation with parenteral only (various)	5–6	10 every 4–6 h (max. 5 days, which includes parenteral doses) In non-elderly patients, initial oral dose of 20	40
Pyrazols			
Celecoxib (Celebrex)	11	Initial 400 followed by another 200 on first day, then 200 twice daily	400

[a]Available both as an over-the-counter preparation and as a prescription drug.
[b]Some experts believe 4,000 mg may be too high.
[c]Up to 1,250 mg on the first day.
[d]Up to 200 mg on the first day.
[e]Some individuals may respond better to 3,200 mg as opposed to 2,400 mg, although well-controlled trials show no better response; consider risk versus benefits when using 3,200 mg/day.
[f]Over-the-counter dose.
[g]Dose for elderly and those under 50 kg (110 lbs).
FDA, Food and Drug Administration; h, hours; IM, intramuscular; IV, intravenous; Nd, no data.
Data from American Pain Society,[24] Anonymous,[40,41] Watkins et al.,[61] and Caldolor.[65]

Opioid Agents

Opioids are often the next logical step in the management of acute pain and cancer-related chronic pain. They also may be an effective treatment option in the management of chronic noncancer pain; however, this continues to be somewhat controversial. Many times a trial of opioids is warranted, but such a trial should not be done without a complete assessment of the pain complaint, including an assessment of the patient's functionality and risk factors for opioid misuse and abuse.[29]

The classification of these agents, their equianalgesic doses, relative histamine-releasing characteristics, pharmacokinetics, and dosing guidelines are outlined in Tables 69–4 and 69–5. Opiate choice should be based on patient acceptance; analgesic effectiveness; and pharmacokinetic, pharmacodynamic, and side-effect profiles (Tables 69–4 and 69–6).

The pharmacologic activity of opioids depends on their affinity for opiate receptors.[14] Therapeutic activities and side effects range from those exhibited by the opiate agonists (e.g., morphine) to those seen with the opiate antagonists (e.g., naloxone). Partial

TABLE 69-4 Opioid Analgesics, Central Analgesics, Opioid Antagonist

Class and Generic Name (Brand Name)	Chemical Source	Relative Histamine Release	Route	Equianalgesic Dose in Adults (mg)	Approximate Onset (min)/ Half-Life (h)
Phenanthrenes (morphine-like agonists)					
Morphine (various)	Naturally occurring	+++	IM	10	10–20/2
			PO	30

[a]Starting dose only (equianalgesia not shown).
[b]Starting doses lower (oxycodone 5–10 mg, meperidine 50–150 mg).
[c]Equivalent PO morphine dose = variable.
[d]For breakthrough pain only.
[e]The equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose.
[f]Starting doses to be used in cases of opioid overdose.
[g]First day of dosing may administer second dose 1 hour after first dose.
IM, intramuscular; IV, intravenous; PO, oral.
Data from American Pain Society,[24] Gutstein and Akil,[30] McPherson,[32] Pasero et al.,[66] Anonymous,[40,41] Tapentadol,[46] Li.[62]

agonists and antagonists (e.g., pentazocine) compete with agonists for opiate receptor sites and, depending on the inherent agonist and antagonist properties, exhibit mixed agonist–antagonist activity. Mixed agonist–antagonist agents with analgesic activity appear to exhibit selectivity for analgesic receptor sites.[30] This may result in analgesia with fewer undesirable side effects. Efficacy and side effects also may further differ among agents because of receptor subtype variability.[31] This μ-receptor subtype variability may explain why some patients respond differently to certain opioids, specifically μ-receptor agonists.[31]

The effects of the opioid analgesics are relatively selective, and at normal therapeutic concentrations, these agents do not affect other sensory modalities,[30] such as sensitivity to touch, sight, or hearing; undesirable side effects may increase as the dose is escalated (Table 69–6). Patients in severe pain may receive high doses of opioids with no unwanted side effects, but as the pain subsides, patients may not tolerate even very low doses.[30] Frequently, when opioids are administered, pain is not eliminated, but its unpleasantness is decreased.[30] Patients report that although their pain is still present, it no longer bothers them.

Opioids share related pharmacologic attributes and exert a profound effect on the CNS and gastrointestinal tract.[30] Mood changes, sedation, nausea, vomiting, decreased gastrointestinal motility, constipation, respiratory depression, dependence, and tolerance are evident in varying degrees with all agents.[3,30] Tolerance to side effects (except to constipation) often develops over time.[3] Some differences exist between the opioids in regards to incidence of side effects. Consideration of these differences assists in selection

TABLE 69-5 Dosing Guidelines

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid Tolerant Patients May Need Dose Modification)	Notes
NSAIDs/ acetaminophen/ aspirin	Dose to maximum before switching to another agent (see Table 69–3)	Used in mild-to-moderate pain May use in conjunction with opioid agents to decrease doses of each Regular alcohol use and of acetaminophen may result in liver toxicity Care must be exercised to avoid overdose when combination products containing these agents are used
Morphine	PO 5–30 mg every 4 h[a] IM 5–20 mg every 4 h[a] IV 5–15 mg every 4 h[a] SR 15–30 mg every 12 h (may need to be every 8 h in some patients) Rectal 10–20 mg every 4 h[a]	Drug of choice in severe pain Use immediate-release product with SR product to control breakthrough pain in cancer patients Typical patient controlled analgesia IV dose is 1 mg with a 10 minute lock out interval Every-24-hour products available (Avinza should not exceed doses of 1,600 mg/day)
Hydromorphone	PO 2–4 mg every 4–6 h[a] IM 1–2 mg every 4–6 h[a] IV 0.5–2 mg every 4 h[a] Rectal 3 mg every 6–8 h[a]	Use in severe pain More potent than morphine; otherwise, no advantages Typical patient controlled analgesia IV dose is 0.2 mg with a 10 minute lock out interval. Every-24-hour product (Exalgo) available
Oxymorphone	IM 1–1.5 mg every 4–6 h[a] IV 0.5 mg every 4–6 h[a] PO immediate-release 5–10 mg every 4–6 h[a] PO extended-release 5–10 mg every 12 h[a]	Use in severe pain No advantages over morphine Use immediate-release product with controlled-release product to control breakthrough pain in cancer or chronic pain patients
Levorphanol	PO 2–3 mg every 6–8 h[a] (Levo-Dromoran) PO 2 mg every 3–6 h[a] (Levorphanol Tartrate) IM 1–2 mg every 6–8 h[a] IV 1 mg every 3–6 h[a]	Use in severe pain Extended half-life useful in cancer patients In chronic pain, wait 3 days between dosage adjustments
Codeine	PO 15–60 mg every 4–6 h[a] IM 15–60 mg every 4–6 h[a]	Use in mild to moderate pain Weak analgesic; use with NSAIDs, aspirin, or acetaminophen, analgesic prodrug
Hydrocodone	PO 5–10 mg every 4–6 h[a]	Use in moderate/severe pain Most effective when used with NSAIDs, aspirin, or acetaminophen Only available as combination product with other ingredients for pain and/or cough
Oxycodone	PO 5–15 mg every 4–6 h[a] Controlled release 10–20 mg every 12 h	Use in moderate/severe pain Most effective when used with NSAIDs, aspirin, or acetaminophen Use immediate-release product with controlled-release product to control breakthrough pain in cancer or chronic pain patients
Meperidine	IM 50–150 mg every 3–4 h[a] IV 5–10 mg every 5 min prn[a]	Use in severe pain Oral not recommended Do not use in renal failure May precipitate tremors, myoclonus, and seizures Monoamine oxidase inhibitors can induce hyperpyrexia and/or seizures or opioid overdose symptoms
Fentanyl	IV 25–50 mcg/h IM 50–100 mcg every 1–2 h[a] Transdermal 25 mcg/h every 72 h Transmucosal (Actiq Lozenge) 200 mcg may repeat × 1, 30 min after first dose is started, then titrate Transmucosal (Fentora Buccal Tablet) 100 mcg, may repeat × 1, 30 min after first dose is started, then titrate	Used in severe pain Do not use transdermal in acute pain Transmucosal for breakthrough cancer pain in patients already receiving or tolerant to opioids. Always start with lowest dose despite daily opioid intake
Methadone	PO 2.5–10 mg every 8–12 h[a] IM 2.5–10 mg every 8–12 h[a]	Effective in severe chronic pain Sedation can be major problem Some chronic pain patients can be dosed every 12 h Equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose. Avoid dose titrations more frequently than weekly in chronic pain maintenance
Propoxyphene	PO 100 mg every 4 h[a] (napsylate) PO 65 mg every 4 h[a] (HCl) (maximum 600 mg daily of napsylate, 390 mg HCl)	Use in moderate pain Weak analgesic; most effective when used with NSAIDs, aspirin, or acetaminophen This drug is not recommended in the elderly Will cause carbamazepine levels to increase 100 mg of napsylate salt = 65 mg of HCl salt
Pentazocine	PO 50–100 mg every 3–4 h[b] (max. 600 mg daily, for those 50 mg tablet containing 0.5 mg of naloxone) PO 25 mg every 4 h[b] (max. 150 mg daily, for those 25 mg tablet containing 325 mg of acetaminophen)	Second-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients Parenteral doses not recommended
Butorphanol	IM 1–4 mg every 3–4 h[b] IV 0.5–2 mg every 3–4 h[b] Intranasal 1 mg (1 spray) every 3–4 h[b] If inadequate relief after initial spray, may repeat in other nostril × 1 in 60–90 min Max. 2 sprays (one per nostril) every 3–4 h[b]	Second-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients

(continued)

TABLE 69-5 Dosing Guidelines (continued)

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid Tolerant Patients May Need Dose Modification)	Notes
Nalbuphine	IM/IV 10 mg every 3–6 h[b] (max. 20 mg dose, 160 mg daily)	Second-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients
Buprenorphine	IM 0.3 mg every 6 h[b] Slow IV 0.3 mg every 6 h[b] May repeat × 1, 30–60 min after initial dose	Second-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients Transdermal delivery systems (5, 10, 20 micrograms/hour) available for every 7 day administration Naloxone may not be effective in reversing respiratory depression
Naloxone	IV 0.4–2 mg	When reversing opiate side effects in patients needing analgesia, dilute and titrate (0.1–0.2 mg every 2–3 min) so as not to reverse analgesia
Tramadol	PO 50–100 mg every 4–6 h[a] If rapid onset not required, start 25 mg/day and titrate over several days Extended release PO 100 mg every 24 h	Maximum dose for nonextended-release, 400 mg/24 h; maximum for extended release, 300 mg/24 h Decrease dose in patient with renal impairment and in the elderly
Tapentadol	PO 50-100 mg every 4–6 h[a]	First day of therapy may administer second dose after the first within 1 h Maximum dose first day 700 mg, max. dose thereafter 600 mg

[a]May start with an around-the-clock regimen and switch to prn if/when the painful signal subsides or is episodic.
[b]May reach a ceiling analgesic effect.
IM, intramuscular; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug; PO, oral; prn, as needed; SR, sustained release; HCL, hydrochloride
Data from American Pain Society,[24] Tapentadol,[46] and Anonymous.[40,41,68]

of the most appropriate agent. 3 The route of administration depends on individual patient needs. In patients who have oral access, the oral route is preferred. However, the onset of analgesic effects for oral medications is approximately 45 minutes, and the peak effect usually occurs 1 to 2 hours after administration.[24] This delay must be a consideration when immediate relief is needed in the management of acute pain. Therefore, in some scenarios, such as acute severe pain (i.e., pain crisis) or when the patient is unable to take oral medications, alternative routes of therapy (e.g., intravenous) may be preferred. The relative potency, defined by the equianalgesic dose, of opioids differs greatly (Table 69–4). 4 Equianalgesic dose tables are often based on single-dose studies without regard for patient variability and should be used only as a guide.[32] True opioid allergies are rare, but Table 69–4 also can be used when treating a patient who is allergic to opiates. Most reactions to opioids, such as itching or rash, are due to the associated histamine release from cutaneous mast cells, not a true allergic or immunoglobulin-E (IgE) or T-cell response.[33] Although caution is always advised, a decrease in potential cross-sensitivity is thought to exist when moving from one opioid structural class to another.[33] The classes are phenanthrenes (morphine-like agonists), phenylpiperidines (meperidine-like agonists), and diphenylheptanes (methadone-like agonists). When considering cross-sensitivity, the mixed agonist–antagonist class acts much like the morphine-like agonists.[33] Reactions due to histamine release may be reduced by choosing agents shown to have less effect on histamine release. Morphine has been associated with the greatest histamine release, whereas agents such as oxycodone and fentanyl typically cause fewer histamine-related reactions (see Table 69–4).

TABLE 69-6 Major Adverse Effects of the Opioid Analgesics

Effect	Manifestation
Mood changes	Dysphoria, euphoria
Somnolence	Sedation, inability to concentrate
Stimulation of chemoreceptor trigger zone	Nausea, vomiting
Respiratory depression	Decreased respiratory rate
Decreased gastrointestinal motility	Constipation
Increase in sphincter tone	Biliary spasm, urinary retention (varies among agents)
Histamine release	Urticaria, pruritus, rarely exacerbation of asthma (varies among agents)
Tolerance	Larger doses for same effect
Dependence	Withdrawal symptoms upon abrupt discontinuation

Data from Stimmel[2] and Gutstein and Akil.[30]

2 5 In the initial stages of acute pain, analgesics should be given around the clock. This should commence after administering a typical starting dose and titrating up or down, depending on the patient's degree of pain and demonstrated side effects (e.g., sedation).[24] As-needed schedules often produce wide swings in analgesic plasma concentrations thatcreate wide swings in pain and sedation. This may initiate a vicious cycle where increasing amounts of pain medications are needed for relief. 5 As the painful state subsides and the need for medication decreases, as-needed schedules may be appropriate. As-needed schedules also may be useful in patients who present with pain that is intermittent or sporadic in nature (Fig. 69–2). When opioids are used in the management of persistent chronic pain, around-the-clock administration schedules should be utilized. As-needed or PRN opioids should be used in conjunction with around-the-clock regimens and when patients experience breakthrough pain. Breakthrough pain is a brief, transitory, exacerbation of moderate to severe pain typically occurring in patients with underlying persistent pain that may otherwise be controlled.[32]

Continuous intravenous and subcutaneous methods of opioid infusion are effective for some postoperative pain, but the probability of unwanted side effects is high, and this technique should be reserved for opioid tolerant patients.[24,34] An alternative method is patient-controlled analgesia (PCA). With this technique, patients can self-administer a preset dose of an intravenous opioid via a pump electronically interfaced with a timing device. Compared with traditional as-needed opioid dosing, PCA yields better pain control, improved patient satisfaction, and relatively few differences in side effects.[35]

Administration of opiates directly into the CNS (e.g., epidural and intrathecal/subarachnoid routes) has shown considerable promise in the control of acute, chronic noncancer, and cancer pain (Table 69–7)[30,36,37]; and is common in both large and small institutions throughout the United States. Because of reports of respiratory depression, pruritus, nausea, vomiting, urinary retention, and hypotension,[37] these methods of analgesia require careful monitoring and are best used by experienced practitioners.

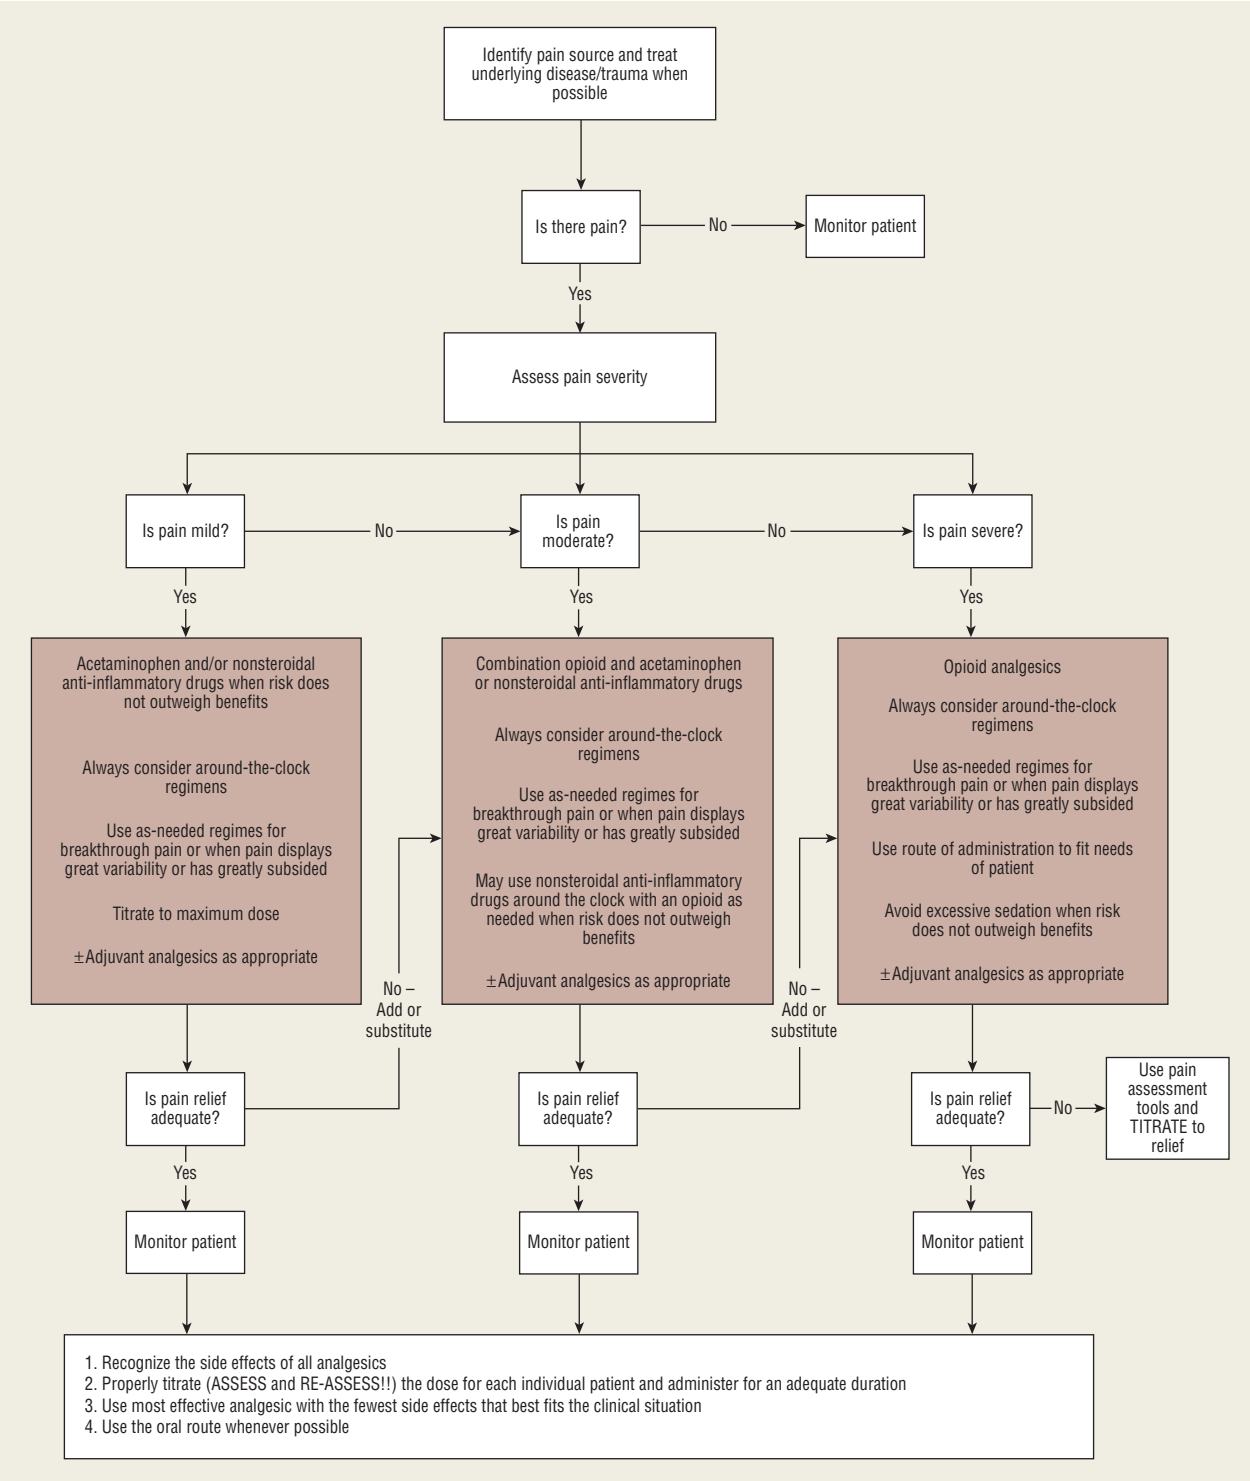

FIGURE 69-2. Algorithm for acute pain. *(Data modified from Omnicare, Inc., Acute Pain Pathway.)*

Respiratory depression is of concern and can occur within minutes with intrathecal fentanyl or manifest as late as 19 hours after a single dose of intrathecal morphine.[37] Guidelines mandate respiratory monitoring for at least 24 hours after a single dose of intrathecal or epidural morphine.[38] Naloxone is used to antagonize this effect. Analgesia and side effects are evident at lower doses when opioids are administered intrathecally instead of epidurally. Intrathecally, single morphine doses of 0.1 to 0.3 mg are common, whereas epidurally, doses of 1 to 6 mg are the norm.[30] These intrathecal and epidural opioids often are administered as a continuous-infusion and/or on a patient-controlled basis. When given simultaneously with intrathecal or epidural local anesthetics such as bupivacaine, they have been proven safe and effective.[37] All agents administered directly into the CNS should be preservative free.

Tolerance, Dependence, Addiction, and Pseudoaddiction A barrier that consistently causes clinicians to misjudge and mistreat pain is the misunderstanding of opioid tolerance, physical dependence, addiction, and pseudoaddiction. Tolerance is the reduction of drug effect over time as a result of exposure to the drug.[39] It develops at different rates and with great patient variability. However, with stable disease, opioid use often stabilizes, and tolerance does not lead

TABLE 69-7 Intraspinal Opioids

Agent	Single Dose (mg)	Onset of Pain Relief (min)	Duration of Pain Relief (h)	Continual Infusion Dose (mg/h)
Epidural route				
Morphine	1–6	30	6–24	0.1–1
Hydromorphone	0.8–1.5	5–8	4–8	0.1–0.3
Fentanyl	0.025–0.1	5	2–8	0.025–0.1
Sufentanil	0.01–0.06	5	2–4	0.01–0.05
Subarachnoid route				
Morphine	0.1–0.3	15	8–34	–
Fentanyl	0.005–0.025	5	3–6	–

Data from American Pain Society[24] and Gutstein and Akil.[30]

to addiction.[39] "Physical dependence is defined by the occurrence of an abstinence syndrome following administration of an antagonist drug or abrupt dose reduction or discontinuation."[39] Clinicians must understand that physical dependence and tolerance are not equivalent to addiction; however, with chronic opioid use, dependence and tolerance are likely to develop.[24] According to Portenoy,[39] "Addiction is best defined as a behavioral pattern characterized as loss of control over drug use, compulsive drug use, and continued use of a drug despite harm." When opioids are being used, these behaviors must be evaluated continually. However, caution is advised when using the term *addiction* because of its many negative connotations, which can lead to a compromised clinician–patient relationship and resulting ineffective pain control.[24,39] In addition, clinicians must be aware that an individual's behaviors may suggest addiction, when in reality the behaviors noted are a reflection of unrelieved pain, this is termed pseudoaddiction.[24] The incidence of addiction varies depending on the patient population. In patients with no history of addiction, the risk of addiction is relatively small.[3] Higher risk for opioid misuse or abuse is associated with personal substance abuse, misuse, addiction or diversion history, a significant family history of substance abuse, and underlying psychiatric diagnoses.[29] In patients with a higher risk for opioid misuse, treatment strategies should be modified. Modifications include baseline and random urine drug screens, patient–provider treatment agreements, a smaller prescription supply, and regular assessment of aberrant behaviors.[29] Combining these approaches with regular and ongoing assessments of pain and functionality may result in improved outcomes.[29]

Morphine and Congeners Despite the availability of several newer agents, morphine remains the prototype opiate analgesic. As new opioid and nonopioid compounds are developed, their efficacy and side-effect profiles are typically compared against morphine as the standard. Many clinicians consider morphine the first-line agent when treating moderate-to-severe pain. Morphine can be given parenterally, orally, or rectally.

Side effects can be numerous, particularly when morphine is first initiated or when doses are significantly increased. Morphine causes nausea and vomiting through direct stimulation of the chemoreceptor trigger zone.[30] Opioid-induced nausea subsides over time.[3] Although euphoria and dysphoria have been reported, morphine's unpleasant effects are more prominent when administered to patients not experiencing pain.[30] As doses of morphine are increased, the respiratory center becomes less responsive to carbon dioxide, causing progressive respiratory depression.[30] This effect is less pronounced in patients being treated for severe or chronic pain.[3] Respiratory depression often manifests as a decrease in respiratory rate (although minute volume and tidal exchange also are affected) and is further compounded because the cough reflex is also depressed.[30] Morphine-induced respiratory depression can be reversed by pure opioid antagonists, such as naloxone.[30] In patients with underlying pulmonary dysfunction, caution must be used as these patients are already using compensatory breathing mechanisms and are at risk for further respiratory compromise.[30] Caution is also urged when combining opiate analgesics with alcohol or other CNS depressants because this combination is potentially harmful and possibly lethal.[30]

Therapeutic doses of morphine have minimal effects on blood pressure, cardiac rate, or cardiac rhythm when patients are supine; however, morphine does produce venous and arteriolar vessel dilation, and orthostatic hypotension may result. Hypovolemic patients are more susceptible to morphine-induced cardiovascular changes (e.g., decreases in blood pressure).[30] Because morphine prompts a decrease in myocardial oxygen demand in ischemic cardiac patients,[30] it is often considered the drug of choice when using opioids to treat pain associated with myocardial infarction.

Morphine decreases the propulsive contractions of the gastrointestinal tract and reduces biliary and pancreatic secretions,[30] resulting in constipation. Morphine-induced spasms of the sphincter of Oddi have been observed.[30] However, the clinical significance of such an occurrence is unclear. Urinary retention is another potential side effect of morphine; tolerance develops to this effect over time.[30] Morphine-induced histamine release often manifests as pruritus, and although not seen often, it may exacerbate bronchospasm in patients with a history of asthma.[30] Therapeutic doses of morphine are not contraindicated in head injury, but drug-induced respiratory depression can increase intracranial pressure. Thus, caution is advised in head trauma patients who are not ventilated because morphine may exaggerate this pressure[30] and cloud the neurologic examination results.

Morphine is metabolized to two major metabolites, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G).[30] M6G contributes to analgesia, whereas M3G may contribute to side effects.[30] The metabolites are renally cleared and can accumulate in patients with renal impairment, contributing to greater side effects.[30] Morphine also affects the hypothalamus inhibiting the release of gonadotropin-relasing hormone, thus decreasing plasma testosterone and cortisol.[30] Although the clinical meaning has not clearly been elucidated, morphine and other opioids also appear to be immunosuppressive.[30]

Hydromorphone is more potent, has better oral absorption characteristics, and is more soluble than morphine, but its overall pharmacologic profile parallels that of morphine. Some clinicians believe hydromorphone is associated with fewer side effects, especially pruritus, compared with other opioids. However, the research is limited and does not conclusively demonstrate a difference in side effects between morphine and hydromorphone. Oxymorphone can be administered orally, rectally, and by injection. Although extended-release and immediate-release oral products have become available, making oxymorphone useful in chronic and acute pain, it offers no pharmacologic advantage over morphine. Levorphanol has an extended half-life, but its overall therapeutic effects are similar to the other agents in this class.

Codeine is a commonly used opiate in the treatment of mild-to-moderate pain. It often is combined with other analgesic products (e.g., acetaminophen). Unfortunately, it has the same propensity to produce side effects as morphine. Hydrocodone is another commonly prescribed opiate and is available for pain only in combination products with other analgesic agents (e.g., acetaminophen, ibuprofen). Its pharmacologic properties are similar to those of morphine. Oxycodone is a useful oral analgesic for moderate-to-severe pain. This is especially true when the product is used in combination with nonopioids. Although oxycodone shares basic morphine characteristics, the availability of an immediate-release and controlled-release oral dosage form also makes it very useful in persistent pain as well as acute pain.

Meperidine and Congeners (Phenylpiperidines) The prototype phenylpiperidine, meperidine, has a pharmacologic profile comparable with that of morphine; however, it is not as potent and has a shorter analgesic duration. Meperidine offers no analgesic advantage over morphine, has greater toxicity (CNS hyperirritability caused by its renally eliminated metabolite normeperidine),[40] and should be limited in use. In particular, avoid long-term usage, and use in patients at greatest risk for toxicity (e.g., elderly patients and those with renal dysfunction).

Fentanyl is a synthetic opioid structurally related to meperidine that is used often in anesthesiology as an adjunct to general anesthesia.[40] This agent is more potent and faster acting than meperidine (Table 69–4). It can be administered parenterally, transmucosally, and transdermally.

Methadone and Congeners Methadone has gained considerable popularity because of its oral efficacy, extended duration of action, and low cost. Although methadone is effective in acute pain,[41] it has gained particular prominence in treating cancer pain[36] and has increasingly been used in the management of chronic noncancer pain.[42] This despite the fact that, with repeated doses, the analgesic duration of action is prolonged,[41] it has an unpredictable half-life, it can cause excessive sedation, and it is difficult to titrate. Properties unique to methadone, compared with other opioids, include the D-isomer's ability to antagonize NMDA receptors, agonist effects at κ- and δ-opioid receptors, and blockade of serotonin and norepinephrine reuptake.[32,42] These properties may prove useful in the treatment of neuropathic and chronic pain or in patients with a maladaptive inflammatory component to their pain. However, few trials have thoroughly evaluated methadone's risks versus benefits.[29] Epidemiologic studies suggest a growing number of methadone related deaths, and cardiac arrhythmias have been associated with methadone, particularly at higher doses or when used concurrently with other agents that prolong QTc intervals.[29] The equianalgesic dose of methadone may decrease with higher doses of the previous opioid,[32] complicating conversions from other opioids to methadone.

CLIINICAL CONTROVERSY

Some clinicians believe that methadone should be tried before other opioids in many chronic pain conditions where an opioid is warranted because they believe that neuropathic pain is often a component. Other clinicians believe that sustained-released morphine or oxycodone are better first choices.

Propoxyphene usually is used in combination with acetaminophen for treatment of mild to moderate pain.[43] Propoxyphene is metabolized to norpropoxyphene, a potentially cardio-toxic metabolite.[30] Propoxyphene has been associated with medication injury in the elderly and its use is discouraged in these patients.[44] The U.S. Food and Drug Administration (FDA) has recently required more specific product labeling outlining this agent's possible risks and is requiring a new safety study to determine its risks versus its benefits.[43]

Opioid Agonist–Antagonist Derivatives Analgesic agents that stimulate the analgesic portion of opioid receptors while blocking or having no effect on the toxicity portion would be considered ideal. The agonist–antagonist derivatives were developed with this in mind. This analgesic class produces analgesia and has a ceiling effect on respiratory depression.[30] These agents also have a lower abuse potential than does morphine, but psychotomimetic responses (e.g., hallucinations and dysphoria, as seen with pentazocine), a ceiling analgesic effect, and a propensity to initiate withdrawal in opioid-dependent populations[30,40] have diminished their widespread clinical use.

Opioid Antagonists The pure opioid antagonist naloxone binds competitively to opioid receptors but does not produce an analgesic or opioid side-effect response. Therefore, it is used most often to reverse the toxic effects of agonist- and agonist–antagonist-derived opioids.

Central Analgesics

Tramadol and tapentadol are the only centrally acting analgesics currently available in the United States. Tramadol binds to μ-opiate receptors and inhibits norepinephrine and serotonin reuptake. Tapentadol also binds the μ-opiate receptor but inhibits largely norepinephrine reuptake. Tramadol is indicated for the relief of moderate to moderately severe pain, while tapentadol is indicated for moderate to severe acute pain.[41]

Both tramadol and tapentadol have side-effect profiles similar to that of the previously mentioned opioid analgesics (e.g., dizziness, nausea, somnolence, and constipation).[45,46] Tapentadol is a schedule II controlled substance, while tramadol is not scheduled.[46] Tapentadol has not been systematically evaluated in patients with seizure, and it should be used with caution in seizure patients.[41] Seizure risk may be elevated in patients taking tramadol.[41] Tramadol, may have a place in treating patients with chronic pain, especially neuropathic pain,[47] while tapentadol may be most useful in the management of acute pain.[41]

Adjuvant Analgesics

Adjuvant analgesics are pharmacologic agents with individual characteristics that make them useful in the management of pain but that typically are not classified as analgesics. Examples of adjuvant analgesics include antidepressants and anticonvulsants. 6 Chronic pain that has a maladaptive inflammatory (e.g., low back pain) and/or neuropathic component (e.g., diabetic neuropathy) may require such agents (Table 69–8). Anticonvulsants (e.g., gabapentin, which may decrease neuronal excitability), tricyclic antidepressants, serotonin and norepinephrine reuptake inhibitor antidepressants (which block the reuptake of serotonin and norepinephrine, thus enhancing pain inhibition), and topically applied local anesthetics (which decrease nerve stimulation) all have been effective in managing chronic pain.[47]

In cancer patients, bone pain can be treated with radiopharmaceuticals. Both strontium-89 and samarium 153Sm lexidronam have been shown to provide pain relief.[41] Although antihistamines, amphetamines, and steroids have been used as adjuvant pain medications,[27] they have demonstrated only limited success as pain relievers.

Combination Therapy

The combination of opioid and nonopioid analgesics often results in analgesia superior to that produced by either agent alone.[26] This facilitates the use of lower doses and a more favorable side-effect profile, and, when needed, this approach is encouraged.

Regional Analgesia

Regional analgesia with properly administered local anesthetics can provide relief of both acute and chronic pain (Table 69–9).[3,37] These agents can be positioned by injection (e.g., in joints, in the epidural or intrathecal space, along nerve roots, or in a nerve plexus) or topically. Lidocaine in the form of a patch has proven effective in treating focal neuropathic pain.[47] Regional application of local

TABLE 69-8 Pharmacologic Management of Chronic Noncancer Pain

Type of Pain	Nonopioids	Opioids	Other Medications	Comments
Chronic low back pain	Acetaminophen	Short-term use for mild-to-moderate flare-ups	Tramadol, TCAs, AEDs	Acetaminophen first; tramadol or opioids in selected patients; AEDs or TCAs may be considered if neuropathic symptoms (evidence weak)
Fibromyalgia	Acetaminophen, NSAIDs	Long-term use not recommended	Tramadol, TCAs; AEDs, SNRIs	Acetaminophen considered first (evidence weak); TCAs, AEDs, SNRIs (stronger evidence); tramadol better alternative than opioids; NSAIDs only with other agents
Neuropathic pain	Acetaminophen or NSAIDs are rarely effective	Considered second-line therapy, are tried after AEDs and/or TCAs,	TCAs, AEDs, SNRIs, tramadol, topical (e.g., 5% lidocaine patch, capsaicin)	TCAs, SNRIs, AEDs, 5% lidocaine patch considered first line; tramadol, and opioids considered second-line agents; capsaicins considered third line

AED, antiepileptic drug; NSAIDs, nonsteroidal antiinflammatory drugs; SNRI, serotonin–norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant.
Data from O'Connor and Dworkin,[47] Am J Manag Care,[63] Chou et al.,[64] and Herndon et al.[67]

anesthetics relieve pain by blocking nerve impulses.[41] High plasma concentrations can cause signs of CNS excitation and depression, including dizziness, tinnitus, drowsiness, disorientation, muscle twitching, seizures, and respiratory arrest.[40] Cardiovascular effects include myocardial depression, hypotension, decreased cardiac output, heart block, bradycardia, arrhythmias, and cardiac arrest.[41] Disadvantages of such methods include the need for skillful technical application, need for frequent administration, and highly specialized followup procedures.

SPECIAL CONSIDERATIONS IN ACUTE PAIN

1 2 3 4 5 The World Health Organization (WHO) recommends a three-step ladder approach using the simplest dosage schedules and medications with the least amount of potential harm based on pain intensity ratings from mild, to moderate, to severe.[27] An acute pain algorithm outlining how to use these principles is given in Figure 69–2. The importance of reassessment and titration during this process cannot be overemphasized.

SPECIAL CONSIDERATIONS IN CANCER PAIN

Managing the pain of cancer encompasses both acute and chronic management techniques. 7 Thus, pharmacologic treatment and psychological therapies are best combined with surgical methods, anesthetic procedures, and supportive care measures in a multidisciplinary approach to pain relief.[48,49] The goal is to provide patients with enough pain amelioration to tolerate diagnostic and therapeutic manipulation and permit the patient to function at a level that will allow freedom of movement and choice.[27] Assessment of the factors given in Table 69–2 also applies to cancer patients. Special attention must be given to continual reassessment of the painful state, adverse effects with medications, and aberrant behaviors. 5 Individualization of therapy is always required.[27] Supportive care, in and outside the hospital, using programs such as hospice, is one of the cancer patient's greatest allies, not only in coping with pain but also in accepting the disease. The positive effect this has on the patient cannot be overstated. Pharmacologic management is the mainstay of therapy, and a typical progression of analgesic use in oncology patients is outlined in Figure 69–3.

TABLE 69-9 Local Anesthetics[a]

Agent (Brand Name)	Onset (min)	Duration (h)
Esters		
Procaine (Novocain, various)	2–5	0.25–1
Chloroprocaine (Nesacaine, various)	6–12	0.5
Tetracaine (Pontocaine)	≤15	2–3
Amides		
Mepivacaine (Polocaine, various)	3–5	0.75–1.5
Bupivacaine (Marcaine, various)	5	2–4
Lidocaine (Xylocaine, various)	<2	0.5–1
Prilocaine (Citanest)	<2	1–2
Ropivacaine[b] (Naropin)	10–30	0.5–6

[a]Unless otherwise indicated, values are for infiltrative anesthesia.
[b]Epidural administration.

SPECIAL CONSIDERATIONS IN CHRONIC NONCANCER PAIN

7 The numerous etiologies that produce chronic noncancer pain make treatment complex, and overall management should be multidisciplinary. Evaluation objectives include establishing an accurate diagnosis, identifying iatrogenic factors, obtaining a comprehensive psychiatric and psychosocial assessment, paying special attention to family and social problems, and obtaining a description of factors that alleviate or exacerbate pain.[2] 8 Given these objectives, placebos should never be used to diagnose pain.[4]

7 In all cases of chronic noncancer pain, an integrated systematic approach (such as that often provided by pain clinics), with a strong emphasis on patient–clinician relationships, is essential. The goal is to improve or maintain the patient's level of functioning, decrease the rate of physical deterioration, decrease pain perception, improve the patient's sense of well-being, improve family and social relationships, and decrease dependency on drug therapy.[2] Patients and clinicians must realize that maximally effective treatment may take months or even years. During this time it may become necessary to use opioids for chronic noncancer pain patients. This has been a source of debate; however, recommendations exist when this modality becomes necessary that includes screening patients for risk of abuse, utilizing pain treatment "agreements," and distinctly outlining the treatment plan with patients.[29]

CLIINICAL CONTROVERSY

Many clinicians believe that some chronic painful conditions (e.g., osteoarthritis) should never be treated with opioids; whereas others believe that when other modalities are not effective or seem to pose more of a risk to that particular patient than does conventional therapy (e.g., NSAIDs), then opioids are necessary.

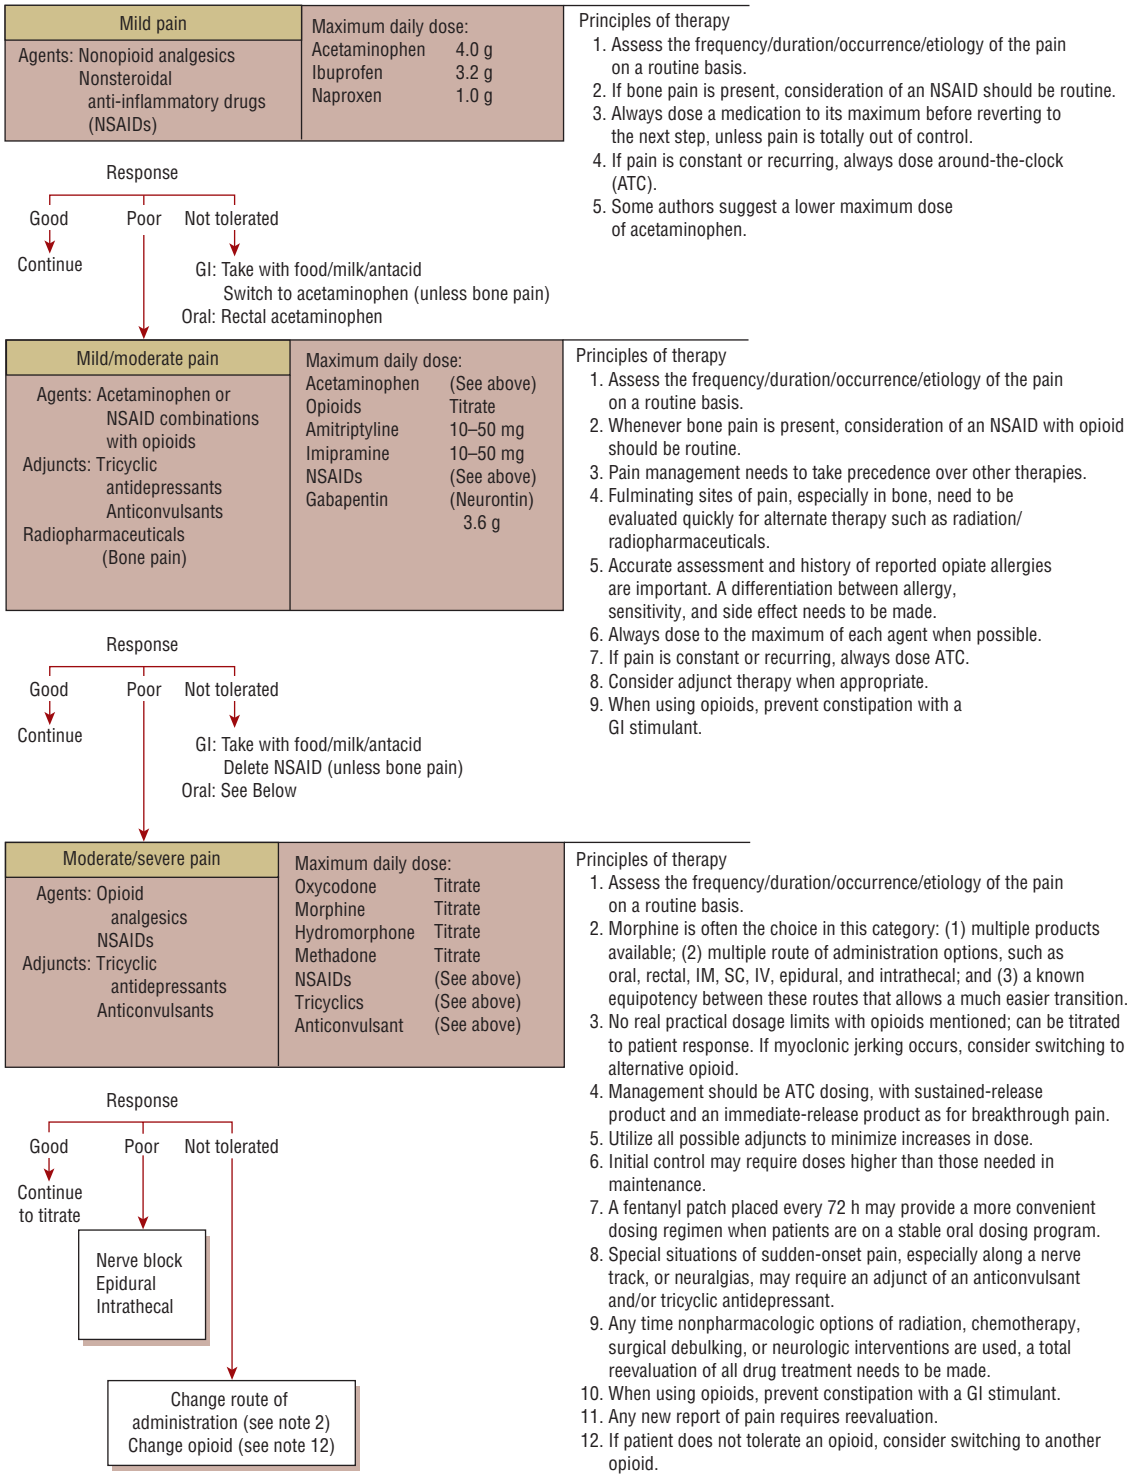

FIGURE 69-3. Algorithm for pain management in oncology patients. *(Data modified from the Kaiser Permanente Algorithm for Pain Management in Patients with Advanced Malignant Disease and reference 36.)*

SPECIAL POPULATIONS

The elderly and the young are at a higher risk for under-treatment because of inability to communicate or rate their pain. It is in these cases that parent or caregiver input becomes paramount to identify changes in behavior which might suggest pain (e.g., fussy, inconsolable, changes in eating patterns, crying out, or agitation). 5 In addition, those living with chronic, debilitating, and life-threatening illnesses need specialized pain control and care that is palliative in nature.[50] Although care must be taken in these populations to ensure that proper individualized treatment plans follow accepted guidelines,[50–53] the key concepts in pain management as outlined in this chapter are the guiding tenets in maximizing pain control.

PHARMACOECONOMIC CONSIDERATIONS

The *suffering* component of pain cannot be overemphasized. Swift relief from acute and cancer pain and well-planned treatment regimens in chronic noncancer pain will allow patients to concentrate

on recovery and regaining control of their lives. Although few well-designed pharmacoeconomic studies have been performed,[54–56] most pain clinicians believe that this approach minimizes time in the hospital and time away from work while maximizing quality of life.

EVALUATION OF THERAPEUTIC OUTCOMES

2 5 The key to treating pain effectively is consistent monitoring for effectiveness (pain relief) versus side effects (e.g., sedation) and titrating treatment accordingly. In acute pain, this often must be done several times per day (in the early stages, hourly), whereas in chronic pain this may occur daily or even weekly. The frequency of evaluation also depends on the drug, the administration route, and other therapies being used. When patients cannot be asked about their pain (e.g., coma), monitoring agitation and heart rate is appropriate. Given the subjective nature of pain, the most successful therapies involve not only frequent patient assessment but also a large degree of patient control (as with PCA). With chronic pain, tools such as the Brief Pain Inventory, Initial Pain Assessment Inventory, McGill Pain Questionnaire, or pain drawings may be helpful.[3]

2 All opioids can cause constipation. The best management of constipation is prevention. Patients should be counseled on the proper intake of fluids and fiber. A stimulating laxative should be added with chronic opioid use. As noted earlier, CNS depressants (e.g., alcohol, benzodiazepines) amplify CNS depression when used with opioid analgesics, and use of these combinations should be discouraged when possible. When the combinations are used, patients should be monitored closely.

CONCLUSIONS

Poor training of healthcare practitioners in pain assessment and management, improper patient education, and inadequate communication among healthcare professionals are some of the reasons for inadequate pain relief. The use of an integrated approach, incorporating the expertise of many disciplines, may well be the most overlooked principle of pain pharmacotherapy. It is the responsibility of all healthcare professionals who deal with pain to work together to ensure proper management.

CHAPTER 70

Headache Disorders

DEBORAH S. MINOR

KEY CONCEPTS

1. Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work.
2. A stratified care approach, in which the selection of initial treatment is based on headache-related disability and symptom severity, is the preferred treatment strategy for the migraineur.
3. Strict adherence to maximum daily and weekly doses of antimigraine medications is essential.
4. Preventive therapy should be considered in the setting of recurring migraines that produce significant disability; frequent attacks requiring symptomatic medication more than twice per week; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury.
5. The selection of an agent for migraine prophylaxis should be based on individual patient response, tolerability, convenience of the drug formulation, and comorbid conditions.
6. Each prophylactic medication should be given an adequate therapeutic trial (usually 2–6 months) to judge its efficacy.
7. A general wellness program and avoidance of migraine triggers should be included in the management plan.
8. After an effective abortive agent and dose have been identified, subsequent treatments should begin with that same regimen.

Headache is one of the most common complaints encountered by healthcare practitioners and among the top three principal reasons given by adults 18 years of age and older for visiting emergency departments in the United States.[1] Headache can be symptomatic of a distinct pathologic process or can occur without an underlying cause. In 2004, the International Headache Society (IHS) updated its classification system and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain[2] (Table 70–1). Designed to facilitate headache diagnosis in clinical practice and research, the IHS classification provides more precise definitions and standardized nomenclature for both the primary (tension-type, migraine, and cluster headache) and secondary (symptomatic of organic disease) headache disorders. This chapter focuses on the management of the primary headache disorders.

Most recurrent headaches are the result of a benign chronic primary headache disorder.[3] Less often, headaches are symptomatic of a serious underlying medical condition, such as infection, cerebral hemorrhage, or brain mass lesion. The peak prevalence of tension-type and migraine headache, the most common of the primary headache disorders, occurs during the most productive years of life (20–55 years of age).[3] Despite the prevalence of these disorders and their associated disability, studies indicate that most headache sufferers do not seek appropriate medical care for their headaches.[4,5] An improved understanding of the diagnosis and pathophysiologic mechanisms of the primary headache disorders, particularly migraine, has led to the development of medications capable of providing rapid relief from moderate to severe attacks. However, a thorough evaluation of the headache history is essential to establish an accurate headache diagnosis and identify patients who can benefit from these specific therapeutic options.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

MIGRAINE HEADACHE

EPIDEMIOLOGY

Results of the American Migraine Prevalence and Prevention Study indicate that 17.1% of women and 5.6% of men in the United States experience one or more migraine headaches per year.[5] The prevalence of migraine varies considerably by age and gender, but the epidemiologic profile has remained stable over the past 15 years.[5] Before the age of 12 years, migraine is more common in boys than in girls, but prevalence increases more rapidly in girls after puberty.[3] After age 12, females are two to three times more likely than males to suffer from migraine. Gender differences in migraine prevalence have been linked to menstruation, but these differences persist beyond menopause. Prevalence is highest in both men and women between the ages of 30 and 49 years.[5] The usual age of onset is 12 to 17 years of age for females and 5 to 11 years for males.[3] In the American Migraine Prevalence and Prevention Study, 93% of those with migraine reported some headache-related disability, and 54% were severely disabled or needed bed rest during an attack.[5] A number of neurologic and psychiatric disorders as well as cardiovascular diseases, including stroke, epilepsy, major depression, sleep apnea, and anxiety disorder, show increased comorbidity with migraine.[3,6] Whether this relationship is causal or representative of a common pathophysiologic mechanism is unknown. The economic burden of migraine is substantial; however, the indirect

TABLE 70-1 International Headache Society Classification System: Focus on Migraine Headache

- Migraine
- Migraine without aura
- Migraine with aura
  - Typical aura with migraine headache (aura lasting <1 hour)
  - Typical aura with nonmigraine headache
  - Typical aura without headache
  - Familial hemiplegic migraine
  - Sporadic hemiplegic migraine
  - Basilar-type migraine
- Childhood periodic syndromes that are commonly precursors of migraine
  - Cyclical vomiting (self-limiting episodic condition)
  - Abdominal migraine (episodic midline abdominal pain attacks lasting 1–72 hours)
  - Benign paroxysmal vertigo of childhood (brief episodic vertigo)
- Retinal migraine (repeated attacks of monocular visual disturbance)
- Complications of migraine
  - Chronic migraine (occurring on ≥15 days per month for >3 months)
  - Status migrainous (debilitating attack lasting >72 hours)
  - Persistent aura without infarction (symptoms persisting >1 week)
  - Migrainous infarction (aura symptoms associated with an ischemic brain lesion)
  - Migraine-triggered seizure
- Probable migraine
  - Probable migraine without aura
  - Probable migraine with aura
  - Probable chronic migraine
- Tension-type headache
- Cluster headache and other trigeminal autonomic cephalalgias
- Other primary headaches
- Headache attributed to head and/or neck trauma
- Headache attributed to cranial or cervical vascular disorder
- Headache attributed to nonvascular intracranial disorder
- Headache attributed to a substance or its withdrawal
- Headache attributed to infection
- Headache attributed to disorder of homeostasis
- Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
- Headache attributed to psychiatric disorder
- Cranial neuralgias and central causes of facial pain
- Other headache, cranial neuralgia, central or primary facial pain

costs from work-related disability far exceed the direct costs associated with treatment.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

The etiologic and pathophysiologic mechanisms of migraine are not completely understood. According to earlier theories, the migraine aura was caused by intracerebral arterial vasoconstriction followed by reactive extracranial vasodilation and associated headache. Although studies of regional blood flow in the brain do not support this vascular hypothesis, the aura phase of migraine is associated with a reduction in cerebral blood flow that begins in the occipital region and moves across the cerebral cortex at a rate of 2 to 3 mm/min.[7,8] However, most clinicians now believe that the positive and negative symptoms of migraine are caused by neuronal dysfunction, not ischemia.[6–8] The neurologic changes of the aura parallel those that occur during cortical spreading depression, a neuronal event characterized by a wave of depressed electrical activity that advances across the brain cortex at a rate consistent with the spread of aura symptoms.[7] Migraine without aura is a neurobiologic disorder.[2] Migraine pain is believed to result from activity within the trigeminovascular system, a network of visceral afferent fibers that arises from the trigeminal ganglia and projects peripherally to innervate the pain-sensitive intracranial extracerebral blood vessels, dura mater, and large venous sinuses[9] (Fig. 70–1). These fibers also project centrally, terminating in the trigeminal nucleus caudalis in the brainstem and upper cervical spinal cord, and thus provide a pathway for nociceptive transmission from meningeal blood vessels into higher centers of the central nervous system (CNS). Activation of trigeminal sensory nerves triggers the release of vasoactive neuropeptides, including calcitonin gene-related peptide (CGRP), neurokinin A, and substance P, from perivascular axons. The released neuropeptides interact with dural blood vessels to promote vasodilation and dural plasma extravasation, resulting in neurogenic inflammation.[6,7] Orthodromic conduction along trigeminovascular fibers transmits pain impulses to the trigeminal nucleus caudalis, where information is relayed further to higher cortical pain centers. Continued afferent input can result in sensitization of these central sensory neurons, producing a hyperalgesic state that responds to previously innocuous stimuli and maintains the headache.[7]

Despite recent advances in understanding of the pathophysiology of headache pain, there is still a considerable lack of knowledge regarding the mechanisms of attack initiation. Although the exact pathophysiology of migraine needs further elucidation, new neuroimaging techniques have provided insight into mechanisms. Previous vascular and neural theories of migraine development have merged into a combined theory of neurovascular mechanisms. Activity within the trigeminovascular system may be regulated in part by serotonergic neurons within the brainstem. Thus, the pathogenesis of migraine may be related to a defect or dysfunction in the activity of neuronal calcium channels mediating serotonin and excitatory neurotransmitter release in brainstem nuclei that modulate cerebral vascular tone and nociception.[7,9] This dysfunction may result in vasodilation of intracranial extracerebral blood vessels and consequent activation of the trigeminovascular system. Future research might further delineate the role of the brainstem as the "migraine generator."

Genetic factors seem to play an important role in susceptibility to migraine attacks. Studies in monozygotic twins suggest approximately 50% heritability of migraine with a multifactorial polygenic basis.[10] Although it is possible for any individual to experience a migraine attack, it is recurrence in the migraineur that is abnormal. Attack occurrence and frequency are governed by CNS sensitivity to migraine-specific triggers or environmental factors. Migraineurs appear to have a lowered threshold of response to specific environmental circumstances as a result of genetic factors that govern the balance of CNS excitation and inhibition at various levels.[10] Thus, trigger factors can be viewed as modulators of the genetic set point that predisposes to migraine headache. The hyperresponsiveness of the migrainous brain may be the result of an inherited abnormality in calcium and/or sodium channels and sodium/potassium pumps that regulate cortical excitability through the release of serotonin and other neurotransmitters.[6,10] Low levels of magnesium or dopamine, increased levels of excitatory amino acids such as glutamate, and alterations in levels of extracellular potassium also can affect the migraine threshold and initiate and propagate the phenomenon of cortical spreading depression.[11]

Serotonin (5-hydroxytryptamine [5-HT]) has long been implicated as an important mediator of migraine headache. Specific populations of 5-HT receptor subfamilies (5-HT_1 to 5-HT_7) appear to be involved in the pathophysiology and treatment of migraine headache.[7] Acute antimigraine drugs such as the ergot alkaloids and triptan derivatives are agonists of vascular and neuronal 5-HT_1 receptor subtypes, resulting in vasoconstriction of meningeal blood vessels and inhibition of vasoactive neuropeptide release and pain signal transmission.[7] Drugs used for

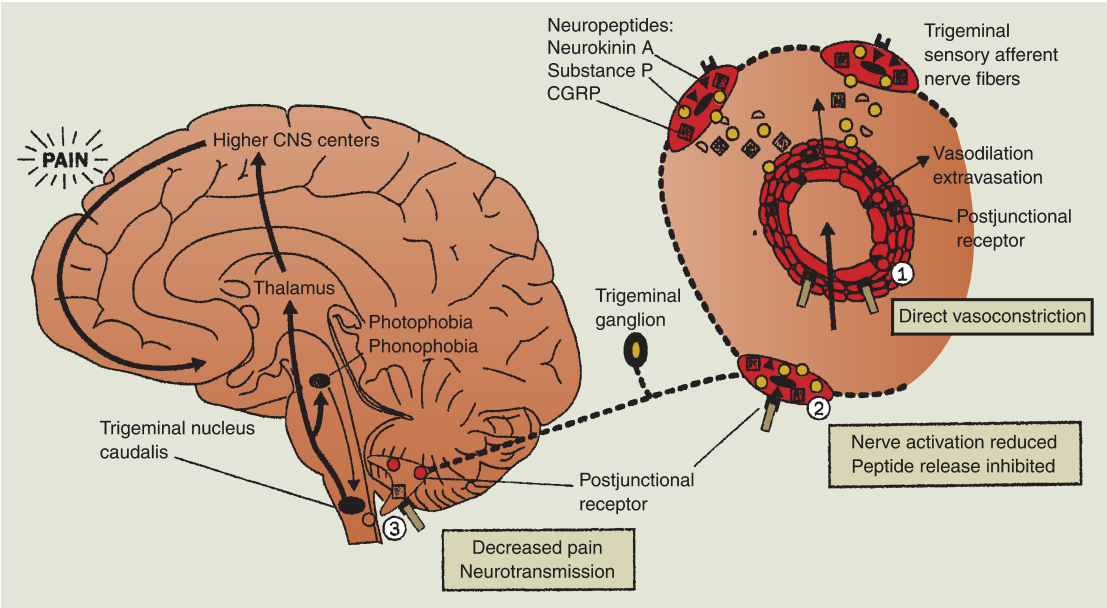

FIGURE 70-1. The pathophysiology of migraine headache. Vasodilation of intracranial extracerebral blood vessels (possibly the result of an imbalance in the brainstem) results in the activation of the perivascular trigeminal nerves that release vasoactive neuropeptides to promote neurogenic inflammation. Central pain transmission may activate other brainstem nuclei, resulting in associated symptoms (nausea, vomiting, photophobia, phonophobia). The antimigraine effects of the 5-$HT_{1B/1D}$ receptor agonists are highlighted at areas *1*, *2*, and *3*. (CGRP, calcitonin gene-related peptide.) *(Reprinted from the Lancet, Vol. 351, Ferrari MD, Migraine, 1043–1051, Copyright © 1998, with permission from Elsevier.)*

migraine prophylaxis also modulate neurotransmitter systems. These actions and benefits in migraine management are consistent with the current understanding of migraine pathophysiology and neurovascular disorders.

CLINICAL PRESENTATION

The migraine attack has been divided into several phases. *Premonitory symptoms* are experienced by approximately 20% to 60% of migraineurs in the hours or days before the onset of headache.[2,7] The previously popular terms *prodrome* and *warning symptoms* should be avoided because these are often used mistakenly to include aura.[2] Premonitory symptoms vary widely among migraineurs but usually are consistent within an individual. Neurologic symptoms (e.g., phonophobia, photophobia, hyperosmia, and difficulty concentrating) are most common, but psychological (e.g., anxiety, depression, euphoria, irritability, drowsiness, hyperactivity, and restlessness), autonomic (e.g., polyuria, diarrhea, and constipation), and constitutional symptoms (e.g., stiff neck, yawning, thirst, food cravings, and anorexia) also are reported.[6–8]

CLINICAL PRESENTATION OF MIGRAINE HEADACHE

General

- Migraine is a common, recurrent, severe headache that interferes with normal functioning. It is a primary headache disorder divided into two major subtypes, migraine without aura and migraine with aura.

Symptoms

- Migraine is characterized by recurring episodes of throbbing head pain, frequently unilateral, that when untreated can last from 4 to 72 hours. Migraine headaches can be severe and associated with nausea, vomiting, and sensitivity to light, sound, and/or movement. Not all symptoms are present at every attack.
- In the headache evaluation, diagnostic alarms should be identified. These include: acute onset of the "first" or "worst" headache ever, accelerating pattern of headache following subacute onset, onset of headache after age 50 years, headache associated with systemic illness (e.g., fever, nausea, vomiting, stiff neck, and rash), headache with focal neurologic symptoms or papilledema, and new-onset headache in a patient with cancer or human immunodeficiency virus infection.

Signs

- A stable pattern, absence of daily headache, positive family history for migraine, normal neurologic examination, presence of food triggers, menstrual association, long-standing history, improvement with sleep, and subacute evolution are all signs of migraine headache. Aura can signal the migraine headache but is not required for diagnosis.

Laboratory Tests

- In selected circumstances and secondary headache presentation, serum chemistries, urine toxicology profiles, thyroid function tests, lyme studies, and other blood tests such as a complete blood count, antinuclear antibody titer, erythrocyte sedimentation rate, and antiphospholipid antibody titer can be considered.

Diagnostic Tests

- Perform a general medical and neurologic physical examination. Check for abnormalities: vital signs (fever, hypertension), funduscopy (papilledema, hemorrhage, and exudates), palpation and auscultation of the head and neck (sinus tenderness, hardened or tender temporal arteries, trigger points, temporomandibular joint tenderness, bruits, nuchal rigidity,

and cervical spine tenderness), and neurologic examination (identify abnormalities or deficits in mental status, cranial nerves, deep tendon reflexes, motor strength, coordination, gait, and cerebellar function). Consider neuroimaging studies in patients with abnormal neurologic examination findings of unknown etiology and in those with additional risk factors warranting imaging.

The migraine *aura,* a complex of positive and negative focal neurologic symptoms that precedes or accompanies an attack, is experienced by approximately 31% of migraineurs on some occasions.[8] The aura typically evolves over 5 to 20 minutes and lasts less than 60 minutes. Headache usually occurs within 60 minutes of the end of the aura. Occasionally, aura symptoms begin at the onset of headache or during the attack. The aura is most often visual and frequently affects half the visual field.[2,8] Visual auras vary in their complexity and can include both positive (scintillations, photopsia, teichopsia, or fortification spectrum) and negative (scotoma, hemianopsia) features. Sensory and motor aura symptoms, such as paresthesias or numbness involving the arms and face, dysphasia or aphasia, weakness, and hemiparesis, also are reported.[7]

Of those with migraine in the United States, 14% experience more than four attacks per month, 63% experience one to four attacks per month, and 23% experience less than one attack per month.[5] Migraine *headache* can occur at any time of the day or night but occurs most often in the early morning hours on awakening. Pain is usually gradual in onset, peaking in intensity over a period of minutes to hours and lasting between 4 and 72 hours. Pain can occur anywhere in the face or head but most often involves the frontotemporal region. The headache is typically unilateral and throbbing or pulsating in nature; however, pain can be bilateral at onset or become generalized during the course of an attack.[2,7,12] Gastrointestinal symptoms almost invariably accompany the headache. During an attack, as many as 90% of migraineurs experience nausea, and emesis occurs in approximately one-third of patients.[7] Other systemic symptoms associated with the headache phase include anorexia, food cravings, constipation, diarrhea, abdominal cramps, nasal stuffiness, blurred vision, diaphoresis, facial pallor, and localized facial, scalp, or periorbital edema. Sensory hyperacuity, manifested as photophobia, phonophobia, or osmophobia, is reported frequently. Because headache pain usually is aggravated by physical activity, most migraineurs seek a dark, quiet room for rest and relief. Impaired concentration, depression, irritability, fatigue, or anxiety often accompany the headache. Once headache pain wanes, patients may experience a *resolution phase* characterized by feeling tired, exhausted, irritable, or listless. Impaired concentration may continue, as well as scalp tenderness or mood changes. Some patients experience depression and malaise, whereas others can feel unusually refreshed or euphoric.[7] The reader is referred to the IHS classification and recent reviews for descriptions of the classic migraine variants and other migraine subtypes[2,7,12,13] (see also Table 70–1).

Although headaches have many potential causes, most are considered to be primary headache disorders. A comprehensive headache history is the most important element in establishing the clinical diagnosis of migraine.[12] A thorough headache history always should be obtained, and information collected should include age at onset, attack frequency and timing, duration of attacks, precipitating or aggravating factors, ameliorating factors, description of neurologic symptoms, characteristics of the headache pain (quality, intensity, location, and radiation), associated signs and symptoms, treatment history, family and social history, and the impact of headaches on daily life.

TABLE 70-2 IHS Diagnostic Criteria for Migraine

Migraine without aura

At least five attacks
Headache attack lasts 4–72 hours (untreated or unsuccessfully treated)
Headache has at least two of the following characteristics:
- Unilateral location
- Pulsating quality
- Moderate or severe intensity
- Aggravation by or avoidance of routine physical activity (e.g., walking or climbing stairs)

During headache at least one of the following:
- Nausea, vomiting, or both
- Photophobia and phonophobia
- Not attributed to another disorder

Migraine with aura (classic migraine)

At least two attacks
Migraine aura fulfills criteria for typical aura, hemiplegic aura, or basilar-type aura
Not attributed to another disorder

Typical aura

Fully reversible visual, sensory, or speech symptoms (or any combination) but no motor weakness
Homonymous or bilateral visual symptoms including positive features (e.g., flickering lights, spot, lines) or negative features (e.g., loss of vision) or unilateral sensory symptoms including positive features (e.g., visual loss, pins and needles) or negative features (i.e., numbness), or any combination
At least one of the following:
- At least one symptom that develops gradually over a minimum of 5 minutes or different symptoms that occur in succession or both
- Each symptom lasts for at least 5 minutes and for no longer than 60 minutes
- Headache that meets criteria for migraine without aura begins during the aura or follows aura within 60 minutes

IHS, International Headache Society.

Secondary headache can be identified or excluded based on the headache history, as well as the results of general medical and neurologic examinations. Diagnostic and laboratory testing also can be warranted in the setting of suspicious headache features or an abnormal examination. The routine use of neuroimaging (computed tomography or magnetic resonance imaging) generally is not indicated in patients with migraine and a normal neurologic examination, but should be considered in patients with an unexplained abnormal neurologic examination or an atypical headache history.[8,12] Because migraine headaches usually begin by the second or third decade of life, headaches beginning after age 50 years suggest an organic etiology such as a mass lesion, cerebrovascular disease, or temporal arteritis. Table 70–2 lists the IHS diagnostic criteria for migraine with and without aura.[2]

TREATMENT

Migraines

DESIRED OUTCOME

Clinicians who care for migraineurs must appreciate the impact of this painful and debilitating disorder on the life of the patient, the patient's family, and the patient's employer. Treatment strategies must address both immediate and long-term goals. 1 Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work. Recurrence of symptoms and treatment-related adverse

TABLE 70-3 Goals of Therapy in Migraine Management

Goals of long-term migraine treatment
Reduce migraine frequency, severity, and disability
Reduce reliance on poorly tolerated, ineffective, or unwanted acute pharmacotherapies
Improve quality of life
Prevent headache
Avoid escalation of headache medication use
Educate and enable patients to manage their disease
Reduce headache-related distress and psychological symptoms
Goals for acute migraine treatment
Treat migraine attacks rapidly and consistently without recurrence
Restore the patient's ability to function
Minimize the use of backup and rescue medications[a]
Optimize self-care for overall management
Be cost-effective in overall management
Cause minimal or no adverse effects

[a]Rescue medications are defined as medications used at home when other treatments fail that permit the patient to get relief without a visit to the physician's office or emergency department.
Data from Diamond and Cady[14] and Matchar et al.[15]

effects should be minimal. Ideally, patients should be able to manage their own headaches effectively without a medical visit. In addition, migraineurs should take an active role in the creation of a long-term formal management plan. An individualized approach to treatment can result in a reduction in attack frequency and severity, thus minimizing headache-related disability and emotional distress and improving the patient's quality of life. Goals of long-term and acute treatment of migraine are listed in Table 70–3.[14,15]

GENERAL APPROACH TO TREATMENT

Nonpharmacologic and pharmacologic interventions are available for the management of migraine headache; however, drug therapy remains the mainstay of treatment for most patients. Pharmacotherapeutic management of migraine can be acute (e.g., symptomatic or abortive) or preventive (e.g., prophylactic). When choosing acute or preventive therapies, the clinician should consider the patient's response to specific medications and their tolerability, as well as coexisting illnesses that can limit treatment choices. Abortive or acute therapies can be migraine-specific (e.g., ergots and triptans) or nonspecific (e.g., analgesics, antiemetics, nonsteroidal antiinflammatory drugs [NSAIDs], and corticosteroids) and are most effective at relieving pain and associated symptoms when administered at the onset of migraine[7,15–17] (Table 70–4). 2 A stratified care approach in which the selection of initial treatment is based on headache-related disability and symptom severity is the preferred treatment strategy for the migraineur.[14,16] Because attack severity varies in individuals, patients may be advised to use nonspecific agents for mild to moderate headache not causing disability while reserving migraine-specific medications for more severe attacks. The absorption and efficacy of orally administered drugs can be compromised by gastric stasis or nausea and vomiting that accompany migraine.[16] Pretreatment with antiemetic agents or the use of nonoral treatment (e.g., suppositories, nasal sprays, or injections) is advisable when nausea and vomiting are severe.[7]

The frequent or excessive use of acute migraine medications can result in a pattern of increasing headache frequency and drug consumption known as *medication-overuse headache* (or *rebound headache*).[2,6,18] The syndrome appears to evolve as a self-sustaining headache-medication cycle in which the headache returns as the medication wears off, leading to the consumption of more drug for relief. The headache history often reflects the gradual onset of an atypical daily or near-daily headache with superimposed episodic migraine attacks. Medication overuse is one of the most common causes of chronic daily headache.[18] Agents most commonly implicated in this syndrome include simple and combination analgesics and opiates. Triptans are also implicated but only in men with a high frequency of headaches.[2,6,18] Discontinuation of the offending agent leads to a gradual decrease in headache frequency and severity and a return of the original headache characteristics. Although detoxification usually can be accomplished on an outpatient basis, hospitalization can be necessary for the control of refractory rebound headache and other withdrawal symptoms (e.g., nausea, vomiting, asthenia, restlessness, and agitation). 3 Regulation of nociceptive systems and renewed responsiveness to therapy usually occur within 2 months following medication withdrawal.[2] Most experts recommend limiting use of acute migraine therapies to *2 or 3 days per week* to avoid the development of medication-misuse headache.[7]

Preventive migraine therapies are administered on a daily basis to reduce the frequency, severity, and duration of attacks and improve responsiveness to symptomatic migraine therapies[7,19–21] (Table 70–5). 4 Preventive therapy should be considered in the setting of recurring migraines that produce significant disability despite acute therapy; frequent attacks occurring more than twice per week with the risk of developing medication overuse headache; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; uncommon migraine variants that cause profound disruption and/or risk of permanent neurologic injury (e.g., hemiplegic migraine, basilar migraine, and migraine with prolonged aura); and patient preference to limit the number of attacks.[7,17] Preventive therapy also may be administered preemptively or intermittently when headaches recur in a predictable pattern (e.g., exercise-induced migraine or menstrual migraine). The efficacy of the various agents used for migraine prophylaxis appears to be similar, but the quality of published data is limited for many commonly used drugs. Only propranolol, timolol, valproate, and topiramate are currently approved by the U.S. Food and Drug Administration (FDA) for the indication.[21,22] 5 Thus the selection of an agent typically is based on its side-effect profile and the patient's comorbid conditions.[7] 6 A therapeutic trial of 2 to 6 months is necessary to judge medication efficacy, but some reduction in attack frequency can be evident by the first month of therapy.[7,23] Drug therapy should be initiated with low doses and gradually increased until a therapeutic effect is achieved or side effects become intolerable. Drug doses for migraine prophylaxis are often lower than those necessary for other indications.[19] Overuse of acute headache medications will interfere with the effects of preventive treatment.[18,22] Prophylactic treatment usually is continued for at least 3 to 6 months after the frequency and severity of headaches have diminished and then is tapered gradually and discontinued.[7,19] Many migraineurs experience fewer and less severe attacks for lengthy periods following discontinuation of prophylactic medications or taper to a lower dose. Figures 70–2 and 70–3 identify treatment and management algorithms for migraine headache.

NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy of acute migraine headache is limited but can include application of ice to the head and periods of rest or sleep, usually in a dark, quiet environment. Preventive management of migraine should begin with the identification and avoidance of factors that consistently provoke migraine attacks in susceptible individuals[2,14,22,24] (Table 70–6). Changes in estrogen levels associated with menarche, menstruation, pregnancy, menopause, oral contraceptive use, and other hormone therapies can trigger, intensify, or alleviate migraine.[23] A headache diary

TABLE 70-4 Acute Migraine Therapies[a]

Medication	Dosage	Comments
Analgesics		
Acetaminophen	1,000 mg at onset; repeat every 4–6 hours as needed	Max. daily dose is 4 g
Acetaminophen 250 mg/aspirin 250 mg/caffeine 65 mg	2 tablets at onset and every 6 hours	Available over-the-counter as Excedrin Migraine
Aspirin or acetaminophen with butalbital, caffeine	1–2 tablets every 4–6 hours	Limit dose to 4 tablets/day and usage to 2 days/week
Isometheptene 65 mg/dichloralphenazone 100 mg/acetaminophen 325 mg (Midrin)	2 capsules at onset; repeat 1 capsule every hour as needed	Max. of 6 capsules/day and 20 capsules/month
Nonsteroidal antiinflammatory drugs		
Aspirin	500–1,000 mg every 4–6 hours	Max. daily dose is 4 g
Ibuprofen	200–800 mg every 6 hours	Avoid doses >2.4 g/day
Naproxen sodium	550–825 mg at onset; can repeat 220 mg in 3–4 hours	Avoid doses >1.375 g/day
Diclofenac potassium	50–100 mg at onset; can repeat 50 mg in 8 hours	Avoid doses >150 mg/day
Ergotamine tartrate		
Oral tablet (1 mg) with caffeine 100 mg	2 mg at onset; then 1–2 mg every 30 minutes as needed	Max. dose is 6 mg/day or 10 mg/week; consider pretreatment with an antiemetic
Sublingual tablet (2 mg)		
Rectal suppository (2 mg) with caffeine 100 mg	Insert ½ to 1 suppository at onset; repeat after 1 hour as needed	Max. dose is 4 mg/day or 10 mg/week; consider pretreatment with an antiemetic
Dihydroergotamine		
Injection 1 mg/mL	0.25–1 mg at onset IM, IV or subcutaneous; repeat every hour as needed	Max. dose is 3 mg/day or 6 mg/week
Nasal spray	One spray (0.5 mg) in each nostril at onset; repeat sequence 15 minutes later (total dose is 2 mg or 4 sprays)	Max. dose is 3 mg/day; prime sprayer 4 times before using; do not tilt head back or inhale through nose while spraying; discard open ampules after 8 hours
Serotonin agonists (triptans)		
Sumatriptan	6 mg subcutaneous at onset; can repeat after 1 hour if needed	Max. daily dose is 12 mg
Injection		
Oral tablets	25, 50, 85 or 100 mg at onset; can repeat after 2 hours if needed	Optimal dose is 50–100 mg; max. daily dose is 200 mg; combination product with naproxen, 85 mg/500 mg
Nasal spray	5, 10, or 20 mg at onset; can repeat after 2 hours if needed	Optimal dose is 20 mg; max. daily dose is 40 mg; single-dose device delivering 5 or 20 mg; administer one spray in one nostril
Zolmitriptan		
Oral tablets	2.5 or 5 mg at onset as regular or orally disintegrating tablet; can repeat after 2 hours if needed	Optimal dose is 2.5 mg; max. dose is 10 mg/day Do not divide ODT dosage form
Nasal spray	5 mg (one spray) at onset; can repeat after 2 hours if needed	Max. daily dose is 10 mg/day
Naratriptan	1 or 2.5 mg at onset; can repeat after 4 hours if needed	Optimal dose is 2.5 mg; max. daily dose is 5 mg
Rizatriptan	5 or 10 mg at onset as regular or orally disintegrating tablet; can repeat after 2 hours if needed	Optimal dose is 10 mg; max. daily dose is 30 mg; onset of effect is similar with standard and orally disintegrating tablets; use 5-mg dose (15 mg/day max.) in patients receiving propranolol
Almotriptan	6.25 or 12.5 mg at onset; can repeat after 2 hours if needed	Optimal dose is 12.5 mg; max. daily dose is 25 mg
Frovatriptan	2.5 or 5 mg at onset; can repeat in 2 hours if needed	Optimal dose 2.5–5 mg; max. daily dose is 7.5 mg (3 tablets)
Eletriptan	20 or 40 mg at onset; can repeat after 2 hours if needed	Max. single dose is 40 mg; max. daily dose is 80 mg
Miscellaneous		
Butorphanol nasal spray	1 spray in 1 nostril (1 mg) at onset; repeat in 1 hour if needed	Limit to 4 sprays/day; consider use only when nonopioid therapies are ineffective or not tolerated
Metoclopramide	10 mg IV at onset	Useful for acute relief in the office or emergency department setting
Prochlorperazine	10 mg IV or IM at onset	Useful for acute relief in the office or emergency department setting

ODT, orally disintegrating tablet.

[a]Limit use of symptomatic medications to 2 or 3 days/week when possible to avoid medication-misuse headache.

Data from Silberstein,[7] Matchar et al.,[15] Smith,[16] and Bigal et al.[17]

that records the frequency, severity, and duration of attacks can facilitate identification of migraine triggers. 7 Patients also can benefit from adherence to a wellness program that includes regular sleep, exercise, and eating habits, smoking cessation, and limited caffeine intake. Behavioral interventions, such as relaxation therapy, biofeedback (often used in combination with relaxation therapy), and cognitive therapy, are preventive treatment options for patients who prefer nondrug therapy or when symptomatic therapies are poorly tolerated, contraindicated, or ineffective.[14,22]

TABLE 70-5 Prophylactic Migraine Therapies

Medication	Dose
β-Adrenergic antagonists	
Atenolol	25–100 mg/day
Metoprolol[a]	50–200 mg/day in divided doses
Nadolol	80–160 mg/day
Propranolol[a,b]	80–240 mg/day in divided doses
Timolol[b]	20–60 mg/day in divided doses
Antidepressants	
Amitriptyline	25–150 mg at bedtime
Doxepin	10–300 mg at bedtime
Nortriptyline	10–150 mg at bedtime
Protriptyline	5–60 mg at bedtime
Fluoxetine	10–80 mg/day
Venlafaxine[a]	75-225 mg/day
Gapapentin	900–2,400 mg/day in divided doses
Topiramate[b]	100 mg/day in divided doses
Valproic acid/divalproex sodium[b]	500–1,500 mg/day in divided doses
Verapamil[a]	240–480 mg/day in divided doses
Nonsteroidal antiinflammatory drugs[c]	
Ketoprofen[a]	150 mg/day in divided doses
Naproxen sodium[a]	550–1,100 mg/day in divided doses
Coenzyme Q10	300 mg/day in divided doses
Feverfew	10–100 mg/day in divided doses
Magesium gluconate	400–600 mg/day in divided doses
Petasites	150 mg/day in divided doses
Vitamin B_2	400 mg/day

[a]Sustained-release formulation available.
[b]FDA approved for prevention of migraine.
[c]Daily or prolonged use limited by potential toxicity.

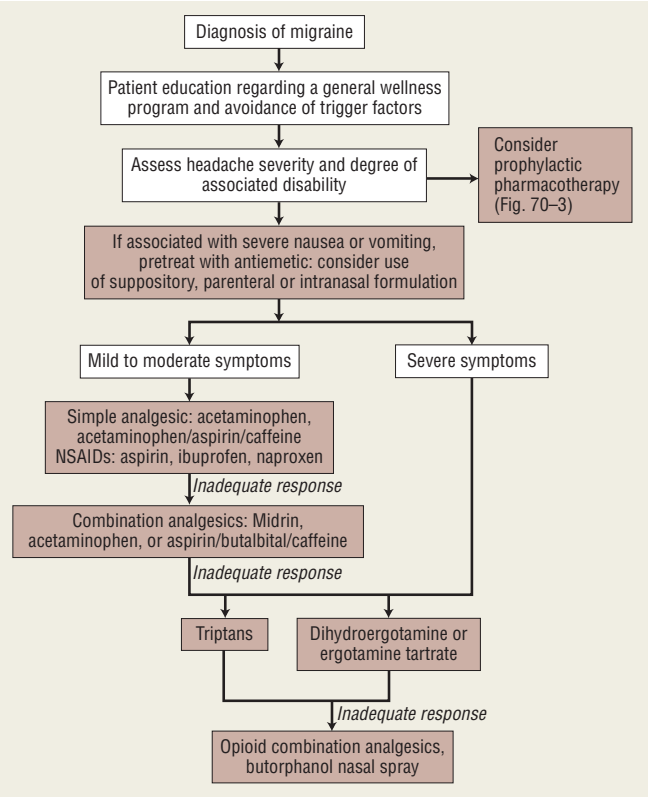

FIGURE 70-2. Treatment algorithm for migraine headaches.

CLINICAL CONTROVERSY

Patients are advised to avoid foods and even medications that are identified as migraine triggers. Despite these recommendations, convincing evidence is lacking for many commonly mentioned dietary triggers.[14] Keeping a headache diary can help patients identify risk factors and personal triggers.

PHARMACOLOGIC MANAGEMENT OF ACUTE MIGRAINE

CLINICAL CONTROVERSIES

The availability of many over-the-counter drugs that were formerly prescription medications enables some migraine patients to self-medicate and delay entry into appropriate medical management. Some clinicians feel that over-the-counter products invite patients to take a less effective step-care approach and avoid being treated according to evidence-based guidelines.[14]

Although controversial, some clinicians argue that the efficacy and tolerability of over-the-counter medications for migraine relief are limited because of patient dissatisfaction with the route of administration, the onset of action, the completeness of pain relief, and the length of suffering and prolonged disability.[14]

Analgesics and NSAIDs

Simple analgesics and NSAIDs are effective medications for the management of many migraine attacks[7,14] (see Table 70–4). They offer a reasonable first-line choice for treatment of mild to moderate migraine attacks or severe attacks that have been responsive in the past to similar NSAIDs or nonopiate analgesics.[14] Of the NSAIDs, aspirin, ibuprofen, naproxen sodium, tolfenamic acid, and the combination of acetaminophen plus aspirin and caffeine have demonstrated the most consistent evidence of efficacy.[7,14] Evidence for other NSAIDs is either limited or inconsistent.[15] Acetaminophen alone is not generally recommended for migraine because the scientific support is not optimal.[7,15] Comparisons with other pharmacotherapeutic classes are limited.

NSAIDs appear to prevent neurogenically mediated inflammation in the trigeminovascular system through the inhibition of prostaglandin synthesis. Metoclopramide can speed the absorption of analgesics and alleviate migraine-related nausea and vomiting.[14] Suppository analgesic preparations are an option when nausea and vomiting are severe.[25] Acute NSAID therapy is associated with gastrointestinal (e.g., dyspepsia, nausea, vomiting, and diarrhea) and CNS side effects (e.g., somnolence, dizziness). NSAIDs should be used cautiously in patients with previous ulcer disease, renal disease, or hypersensitivity to aspirin.[15,26]

The over-the-counter combination of acetaminophen, aspirin, and caffeine was approved for the treatment of migraine in the United States because of its proven efficacy in relieving migraine pain and associated symptoms.[15,17] Aspirin and acetaminophen are also available in prescription combination products containing a short-acting barbiturate (butalbital) or narcotic (codeine, propoxyphene). No randomized, placebo-controlled studies support the efficacy of butalbital-containing products in the treatment of migraine. The use of butalbital-containing analgesics or narcotics should be limited because of concerns about overuse, medication-overuse headache, and withdrawal.[7,14,26] Midrin, a combination of acetaminophen, isometheptene mucate (a sympathomimetic

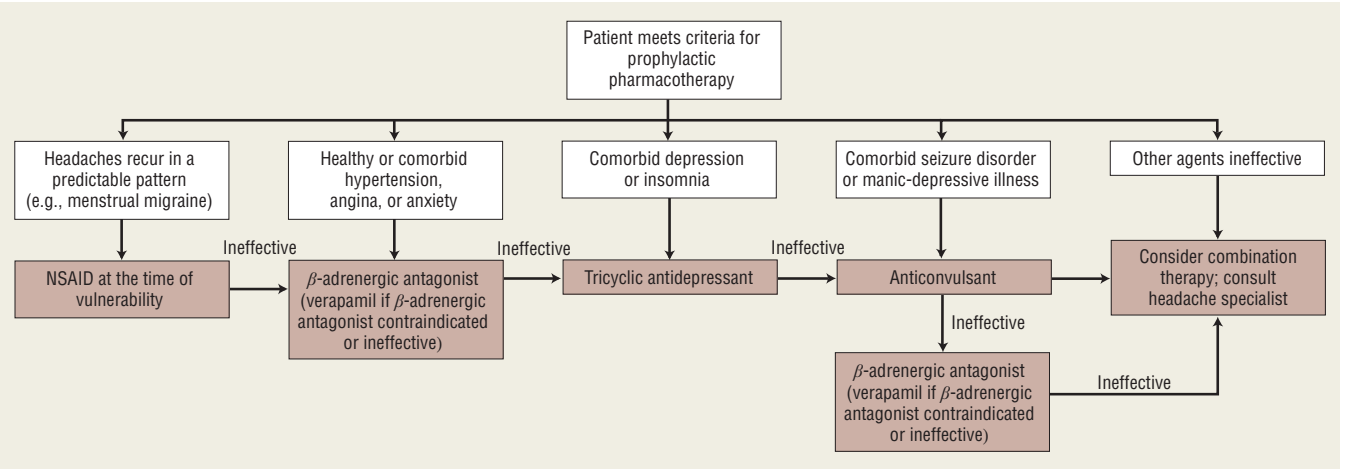

FIGURE 70-3. Treatment algorithm for prophylactic management of migraine headaches. (NSAID, nonsteroidal antiinflammatory drug.)

amine), and dichloralphenazone (a chloral hydrate derivative), has demonstrated modest benefits in placebo-controlled studies and generally is viewed as an alternative for patients with mild to moderate migraine attacks.[15,17] Although frequent consumption of aspirin or acetaminophen alone can result in medication-overuse headache, combination analgesics appear to pose a greater risk.[7,26]

Opiate Analgesics

Narcotic analgesic drugs (e.g., meperidine, butorphanol, oxycodone, and hydromorphone) are effective but generally should be reserved for patients with moderate to severe infrequent headaches in whom conventional therapies are contraindicated or as "rescue medication" after patients have failed to respond to conventional therapies.[7] Frequent use of narcotic analgesics can lead to the development of dependency and rebound headache.[26] The intranasal formulation of butorphanol, a synthetically derived opioid agonist-antagonist, is a treatment option but should be reserved for use only as an alternative to frequent office or emergency department visits for injectable migraine therapies. Opioid therapy should be supervised closely.[16,17]

TABLE 70-6 Commonly Reported Triggers of Migraine

Food triggers
Alcohol
Caffeine/caffeine withdrawal
Chocolate
Fermented and pickled foods
Monosodium glutamate (e.g., in Chinese food, seasoned salt, and instant foods)
Nitrate-containing foods (e.g., processed meats)
Saccharin/aspartame (e.g., diet foods or diet sodas)
Tyramine-containing foods
Environmental triggers
Glare or flickering lights
High altitude
Loud noises
Strong smells and fumes
Tobacco smoke
Weather changes
Behavioral–physiologic triggers
Excess or insufficient sleep
Fatigue
Menstruation, menopause
Sexual activity
Skipped meals
Strenuous physical activity (e.g., prolonged overexertion)
Stress or post-stress

Data from Diamond and Cady,[14] Buse et al.,[22] and Kelman.[24]

Antiemetics

Adjunctive antiemetic therapy is useful for combating the nausea and vomiting that accompany migraine headaches and the medications used to treat attacks (e.g., ergotamine tartrate). A single dose of an antiemetic, such as metoclopramide, chlorpromazine, or prochlorperazine, administered 15 to 30 minutes before ingestion of oral abortive migraine medications is often sufficient. Suppository preparations are available when nausea and vomiting are particularly prominent. Metoclopramide is also useful to reverse gastroparesis and improve absorption from the gastrointestinal tract during severe attacks.[15,16]

In addition to antiemetic effects, dopamine antagonist drugs also have been used successfully as monotherapy for the treatment of intractable headache (see Table 70–4). Prochlorperazine administered by the intravenous and intramuscular routes and intravenous metoclopramide provided more effective pain relief than placebo. Chlorpromazine also has provided relief of migraine headache when administered parenterally at doses of 12.5 to 37.5 mg. Domperidone has a possible role for preemptive treatment of migraine. The precise mechanism of action for these agents is unknown. The dopamine antagonists offer an alternative to the narcotic analgesics for the treatment of refractory migraine. Drowsiness and dizziness were reported occasionally and extrapyramidal side effects were reported infrequently in migraine trials.[15,25]

Miscellaneous Nonspecific Medications

Corticosteroids can be considered as rescue therapy for status migrainous (a severe, continuous migraine that can last up to 1 week).[7,15] Intravenous or intramuscular dexamethasone at a dose of 10 to 25 mg has also been used as an adjunct to abortive therapy.[25,27]

Limited studies suggest a role for intranasal lidocaine in the treatment of acute migraine headache.[15] Intranasal lidocaine, 1 to 4 drops of a 4% solution, provides rapid pain relief within 15 minutes of administration, but headache recurrence is common. Adverse effects generally are limited to local irritation, an unpleasant taste, and numbness of the throat.

Preliminary investigations of intramuscular droperidol have yielded favorable results in the treatment of acute migraine headache.[7] Future studies might establish a more defined role for this agent in migraine management.

Ergot Alkaloids and Derivatives

Ergotamine tartrate and dihydroergotamine are useful and can be considered for the treatment of moderate to severe migraine attacks (see Table 70–4). These drugs are nonselective 5-HT_1 receptor agonists that constrict intracranial blood vessels and inhibit the development of neurogenic inflammation in the trigeminovascular system.[7] Central inhibition of the trigeminovascular pathway is also reported as well as agonist activity at dopaminergic receptors. Venous and arterial constriction occur with therapeutic doses, but ergotamine tartrate exerts more potent arterial effects than dihydroergotamine.[14,17,26]

Ergotamine tartrate is available for oral, sublingual, and rectal administration. Oral and rectal preparations contain caffeine to enhance absorption and potentiate analgesia. Some patients respond preferentially to rectal dosing.[7,14] Dosage requirements should be titrated strictly to establish an effective but subnauseating dose for future attacks. Ergotamine is most effective when administered early in the migraine attack. Despite widespread clinical use since 1926, evidence supporting the efficacy of ergotamine in migraine is inconsistent.[7,14]

Dihydroergotamine is available for intranasal and parenteral administration by the intramuscular, subcutaneous, and intravenous routes.[7] Parenteral dihydroergotamine was viewed previously as inpatient or emergency department treatment for moderate to severe migraine or intractable headache, but patients can be trained to self-administer dihydroergotamine intramuscularly or subcutaneously. Clinical opinion suggests its use is relatively safe and effective when compared with other migraine therapies.[15]

Nausea and vomiting (resulting from stimulation of the chemoreceptor trigger zone) are among the most common adverse effects of the ergotamine derivatives. Pretreatment with an antiemetic agent should be considered with ergotamine and intravenous dihydroergotamine therapy. Other common side effects include abdominal pain, weakness, fatigue, paresthesias, muscle pain, diarrhea, and chest tightness. Rarely, symptoms of severe peripheral ischemia (ergotism), including cold, numb, painful extremities, continuous paresthesias, diminished peripheral pulses, and claudication can result from the vasoconstrictor effects of the ergot alkaloids. Gangrenous extremities, myocardial infarction, hepatic necrosis, and bowel and brain ischemia have also been reported. Dihydroergotamine is rarely associated with such side effects.[14,16,26] Triptans and ergot derivatives should not be used within 24 hours of each other.[26] Ergotamine derivatives are contraindicated in patients with renal or hepatic failure; coronary, cerebral, or peripheral vascular disease; uncontrolled hypertension; sepsis; and in women who are pregnant or nursing.[7,25] Dihydroergotamine does not appear to cause rebound headache, but dosage restrictions for ergotamine tartrate should be observed strictly to prevent this complication.[7]

Serotonin Receptor Agonists (Triptans)

Introduction of the serotonin receptor agonists, or triptans, represented a significant advance in migraine pharmacotherapy. The first member of this class, sumatriptan, and the second-generation agents zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan are selective agonists of the 5-HT_{1B} and 5-HT_{1D} receptors. Relief of migraine headache is the result of three key actions: normalization of dilated intracranial arteries through enhanced vasoconstriction, peripheral neuronal inhibition, and inhibition of transmission through second-order neurons of the trigeminocervical complex.[14,26,28] These agents also display varying affinity for 5-HT_{1A}, 5-HT_{1E}, and 5-HT_{1F} receptors. The triptans are appropriate first-line therapy for patients with mild to severe migraine and are used for rescue therapy when nonspecific medications are ineffective.[7]

Sumatriptan, the most extensively studied acute therapy, is available for subcutaneous, oral, and intranasal administration.[28] Subcutaneous sumatriptan is consistently superior to placebo in alleviating migraine headache and associated symptoms, with relief reported in 69% of patients at 1 hour (48%–49% pain-free) in a meta-analysis of placebo-controlled studies.[7] In addition to enhanced efficacy, subcutaneous sumatriptan has a more rapid onset of action when compared with the oral formulation.[7,28] The subcutaneous injection is packaged as an autoinjector device for self-administration by patients. Intranasal sumatriptan provides a faster onset of effect than the oral formulation and produces similar rates of response (relief in 61% of patients at 2 hours) in placebo-controlled studies.[7]

The second-generation triptans appear to offer an improved pharmacokinetic and pharmacodynamic profile compared with oral sumatriptan. In general, these agents have higher oral bioavailability and longer half-lives than oral sumatriptan, which theoretically could improve within-patient treatment consistency and reduce headache recurrence[7,16,28] (Table 70–7). Frovatriptan and naratriptan have the longest half-lives and a slower onset of action compared with other triptans. This may make them more suitable for patients that have migraine attacks of a slow onset and longer duration. Faster-acting triptans are better when a rapid onset is necessary. Despite the fact that oral absorption can be delayed during migraine attacks, most patients prefer oral formulations, primarily due to convenience.[7,16,28]

Results of placebo-controlled studies with each of the second-generation agents reveal somewhat comparable 2-hour response rates. Direct comparative clinical trials are necessary to determine their relative efficacy, but these are available for only a few of the triptans. A recent meta-analysis summarizes the efficacy and tolerability of the oral triptans across published and unpublished studies. At all marketed doses, the oral triptans are effective

TABLE 70-7 Pharmacokinetic Characteristics of Triptans

Drug	Half-Life (hours)	Time to Maximal Concentration (t_{max})	Bioavailability (%)	Elimination
Almotriptan	3–4	1–3 hours	70	MAO-A, CYP3A4, CYP2D6
Eletriptan	5	1–1.25 hours	50	CYP3A4
Frovatriptan	25	2–4 hours	24–30	Mostly unchanged, CYP1A2
Naratriptan	5–6	2–3 hours	63–74	Largely unchanged, CYP450 (various isoenzymes)
Rizatriptan	2–3		40–45	MAO-A
Oral tablets		1–1.5 hours		
Disintegrating		1.6–2.5 hours		
Sumatriptan	2			MAO-A
SC injection		12–15 minutes	96	
Oral tablets		2.5 hours	14	
Nasal spray		1–2.5 hours	16	
Zolmitriptan	3		40	CYP1A2, MAO-A
Oral		2–2.5 hours		
Disintegrating		3 hours		
Nasal		4 hours		

CYP, cytochrome P450; MAO-A, monoamine oxidase type A.
Data from Silberstein,[7] Smith,[16] and Matthew and Loder.[28]

and well tolerated. Across studies for sumatriptan 100 mg, mean results were a 2-hour headache response of 59%, with 29% pain-free at 2 hours, 20% sustained pain-free, and 67% consistency. Compared with sumatriptan 100 mg, rizatriptan 10 mg showed better efficacy and consistency and similar tolerability; eletriptan 80 mg showed better efficacy, similar consistency, but lower tolerability; almotriptan 12.5 mg showed similar efficacy at 2 hours but better other results; naratriptan 2.5 mg and eletriptan 20 mg showed lower efficacy and better tolerability; and zolmitriptan 2.5 and 5 mg, eletriptan 40 mg, and rizatriptan 5 mg all showed similar results. Available data suggest lower efficacy for frovatriptan, although it has the longest half-life of the triptans.[7,17,28]

Clinical response to the triptans can vary considerably among individual patients. Individual responses cannot be predicted, and if one triptan fails, a patient can be switched successfully to another triptan.[7] 8 After an effective agent and dose have been identified, subsequent treatments should begin with that same regimen. Combination therapy may also improve response rates and diminish migraine recurrence. A proprietary formulation of sumatriptan 85 mg plus naproxen 500 mg in a single tablet was more effective in clinical trials for headache relief and sustained pain-free response than either agent as monotherapy.[16,25]

Side effects to the triptans are common but usually mild to moderate in nature and of short duration. Adverse effects are consistent among the class and include paresthesias, fatigue, dizziness, flushing, warm sensations, and somnolence. Local side effects are reported with the subcutaneous (minor injection-site reactions) and intranasal (taste perversion, nasal discomfort) routes. Up to 15% of patients receiving a triptan consistently report "chest symptoms," including tightness, pressure, heaviness, or pain in the chest, neck, or throat. The mechanism of these symptoms is unknown, but a cardiac source of pain seems unlikely in most patients.[17,26] However, all triptans are partial agonists of human 5-HT coronary artery receptors in vitro, resulting in a small but significant vasoconstrictor response. Adverse cardiac events are rare with only isolated cases of myocardial infarction and coronary vasospasm with ischemia reported. Myocardial ischemia is unlikely in patients with normal coronary vasculature because 5-HT_{1B} receptors mediate less than 25% of the overall vasoconstrictor potential of the coronary vessels.[17] The triptans are contraindicated in patients with a history of ischemic heart disease (e.g., angina pectoris, Prinzmetal's angina, or previous myocardial infarction), uncontrolled hypertension, and cerebrovascular disease. Patients at risk for unrecognized coronary artery disease should use triptans with caution. Postmenopausal women, men older than 40 years of age, and patients with uncontrolled risk factors should receive a cardiovascular assessment prior to triptan use and have initial doses administered under medical supervision.[16,25] Triptans are also contraindicated in patients with hemiplegic and basilar migraine. The triptans should not be given within 24 hours of the ergotamine derivatives. Administration of sumatriptan, rizatriptan, and zolmitriptan within 2 weeks of therapy with monoamine oxidase inhibitors (MAOIs) is not recommended. Eletriptan should not be administered with cytochrome P450 3A4 inhibitors such as macrolide antibiotics, antifungals, and some antiviral therapies. Concomitant therapy with the selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) (e.g., duloxetine, venlafaxine, mirtazepine, and sibutramine) can potentially cause serotonin syndrome. Regulatory agencies caution against concurrent administration although it appears the likelihood of CNS adverse events is extremely low. The potential risk of these combinations should be carefully considered and discussed with the patient.[16,26,29] Frequent use of the triptans has been associated with the development of medication-misuse headache.[14,15]

PROPHYLACTIC PHARMACOLOGIC THERAPY

β-Adrenergic Antagonists

β-Adrenergic antagonists are among the most widely used drugs for migraine prophylaxis. Propranolol, nadolol, timolol, atenolol, and metoprolol have proven efficacy in controlled clinical trials, reducing the frequency of attacks by 50% in 60% to 80% of patients[19] (see Table 70–5). Because the relative efficacy of the individual agents has not been established, selection of a β-blocker can be based on β-selectivity, convenience of the formulation, and tolerability. β-Blockers with intrinsic sympathomimetic activity are ineffective for migraine prophylaxis.[19] Although their precise mechanism of antimigraine action is unknown, β-blockers may raise the migraine threshold by modulating adrenergic or serotonergic neurotransmission in cortical or subcortical pathways. Though not first-line treatment for hypertension or anxiety, β-blockers may be useful along with other therapy in patients with comorbid anxiety, hypertension, or angina.[23] Side effects can include drowsiness, fatigue, sleep disturbances, vivid dreams, memory disturbance, depression, impotence, bradycardia, and hypotension. β-Blockers should be used with caution in patients with congestive heart failure, peripheral vascular disease, atrioventricular conduction disturbances, asthma, depression, and diabetes.[7,19,23]

Antidepressants

The beneficial effects of antidepressants in migraine are independent of their antidepressant activity and may be related to downregulation of central 5-HT_2 receptors, increased levels of synaptic norepinephrine, and enhanced endogenous opiod receptor actions.[30] Amitriptyline, the most widely studied antidepressant for migraine prophylaxis, has demonstrated efficacy in placebo-controlled and comparative studies.[19] Use of other antidepressants is based primarily on clinical and anecdotal experience (see Table 70–5). Other tricyclic antidepressants (TCAs) that have been used successfully for migraine prophylaxis include doxepin, nortriptyline, and protriptyline.[19] Anticholinergic side effects are common and limit use of these agents in patients with benign prostatic hyperplasia and glaucoma. Evening doses are preferred because of associated sedation. Increased appetite and weight gain can occur. Orthostatic hypotension and cardiac toxicity (slowed atrioventricular conduction) also are reported occasionally. The more favorable side-effect profile of nortriptyline and protriptyline could prove advantageous in patients who are particularly intolerant of the anticholinergic and sedative side effects of amitriptyline.[19]

SSRIs have not been studied extensively or proven consistently effective for the preventive treatment of migraine headaches.[19,23] Fluoxetine is the most studied SSRI for migraine prevention, but definitive benefit has not been demonstrated in a rigorous clinical study. Prospective data evaluating the other SSRIs (e.g., sertraline, paroxetine, fluvoxamine, and citalopram) are lacking.[7,19,30] These agents should not be considered as first- or second-line medications for the management of migraine, but they may be useful in patients with comorbid depression combined with, for example, an anticonvulsant for migraine prophylaxis.[23] A recent study suggests a possible benefit with venlafaxine, a SNRI.[20] Again, the potential risk of serotonin syndrome should be considered in patients using SSRIs or SNRIs along with a triptan.[16,29]

MAOIs, such as phenelzine, have been used in the management of refractory headache, but their complex adverse-effect profile limits their use to experienced prescribers. Strict adherence to a tyramine-free diet is necessary to avoid potentially life-threatening hypertensive crisis.[19,22] The reader is referred to Chapter 77 for dietary and concurrent medication restrictions for patients taking MAOIs.

Anticonvulsants

Anticonvulsant medications have emerged as important therapeutic options for migraine prophylaxis with valproate, divalproex, topiramate, and gabapentin all demonstrating efficacy. The beneficial effects of these agents are likely caused by multiple mechanisms of action, including enhancement of γ-aminobutyric acid (GABA)–mediated inhibition, modulation of the excitatory neurotransmitter glutamate, and inhibition of sodium and calcium ion channel activity.[21,30] Anticonvulsants are particularly useful in migraineurs with comorbid seizures, anxiety disorder, or manic-depressive illness.[19] The efficacy of valproic acid and divalproex sodium (a 1:1 molar combination of valproate sodium and valproic acid) has been demonstrated in multiple placebo-controlled studies. Nausea and vomiting, the most common early side effects, are self-limited and appear to be less common with divalproex sodium and gradual titration of doses. Alopecia, tremor, asthenia, somnolence, and weight gain are also common complaints.[7,17] The extended-release formulation of divalproex sodium is administered once daily and is better tolerated than the enteric-coated formulation.[20] Hepatotoxicity is the most serious side effect of valproate therapy, but the risk appears to be low in migraineurs (e.g., patients older than 10 years of age who are receiving monotherapy and have no underlying metabolic or neurologic disorder). Baseline liver function tests should be obtained, but routine follow-up studies are not necessary in asymptomatic adults on monotherapy.[7] Regular follow-up is necessary, however, for dosage adjustments and monitoring of effects.[19] Valproate is contraindicated in pregnant women (owing to potential teratogenicity) and patients with a history of pancreatitis or chronic liver disease. Although valproate level determinations can be useful for assessing compliance and toxicity, a recent study suggests that serum levels of less than 50 mcg/mL (346 μmol/L) (usual therapeutic level is 50–100 mcg/mL [346 to 693 μmol/L]) can provide similar benefit to higher levels. Doses of 500 to 1,000 mg per day are effective for many patients.[1]

Topiramate is the most extensively studied medication to date for migraine prophylaxis. Efficacy and improvements in health-related quality of life including daily work, home, and social activities have been demonstrated in several placebo-controlled studies.[19,22] To minimize adverse effects, topiramate should be initiated at a low dose, 25 mg, and titrated slowly up to a maximum daily dose of 200 mg. The target dose for migraine prevention is 100 mg daily for most patients. The benefits of topiramate are observed as early as two weeks after initiation of therapy, with significant reductions in migraine frequency within the first month. Approximately 50% of patients treated to target doses are responders (≥50% reduction in mean headache frequency). Treatment-emergent adverse events associated with topiramate include paresthesia, fatigue, anorexia, diarrhea, weight loss, hypesthesia, difficulty with memory, language problems, taste perversion, and nausea. Paresthesia is the most common adverse event, occurring in about half of patients at target doses. Weight loss, occurring in 9% to 12% of patients, is a unique adverse effect, as weight gain is a common reason to discontinue other preventive medications. Topiramate should be used with caution in patients with a history of kidney stones.[19,31]

A recent study suggests that gabapentin also may be an effective agent for migraine prevention in patients achieving a daily dose of 2,400 mg.[19] Somnolence and dizziness were the most commonly reported adverse events. Preliminary studies suggest a possible role for other anticonvulsants, including tiagabine, levetiracetam, and zonisamide; however, further clinical studies are needed to confirm their usefulness in migraine prophylaxis.[19,21]

Calcium Channel Blockers

The calcium channel blockers generally are considered second- or third-line options for preventive treatment when other drugs with established clinical benefit are ineffective or contraindicated. Verapamil is the most widely used calcium channel blocker for preventive treatment, but it provided only modest benefit in decreasing the frequency of attacks in two placebo-controlled studies.[7,19] The therapeutic effect of verapamil may not be noted for up to 8 weeks after initiation of therapy. Side effects of verapamil can include constipation, hypotension, bradycardia, atrioventricular block, and exacerbation of congestive heart failure. Evaluations of nifedipine, nimodipine, diltiazem, nisoldipine, nicardipine, and amlodipine have yielded equivocal results.[17,19,21]

NSAIDs

NSAIDs are modestly effective for reducing the frequency, severity, and duration of migraine attacks, but potential gastrointestinal and renal toxicity limit the daily or prolonged use of these agents.[17,20] Consequently, NSAIDs have been used intermittently to prevent headaches that recur in a predictable pattern, such as menstrual migraine. Administration of NSAIDs in the perimenstrual period can be beneficial in women with true menstrual migraine. NSAIDs should be initiated 1 to 2 days prior to the expected onset of headache and continued during the period of vulnerability.[23,31] If long-term NSAID therapy is initiated, monitoring of renal function and occult blood loss is necessary.

Miscellaneous Prophylactic Agents

A double-blind, placebo-controlled study demonstrated the efficacy of riboflavin (vitamin B_2) 400 mg daily in migraine prophylaxis. Riboflavin was well tolerated and associated with 50% or greater improvement in attack frequency in 54% of patients. However, the benefits of therapy became significant only after 3 months.[19,31] The angiotensin-converting enzyme inhibitor lisinopril and the angiotensin II receptor blocker candesartan provided effective migraine prophylaxis in recent double-blind, placebo-controlled, crossover studies of these agents.[31] Further research is needed to establish the safety and efficacy of the herbal medication feverfew (*Tanacetum parthenium*) because studies to date have yielded inconsistent and conflicting results.[19,31] At least two placebo-controlled studies have concluded that petasites, an extract from the plant *Petasites hybridus*, may be an effective preventive treatment for migraine.[19,31] Coenzyme Q10 was effective for migraine prevention and well tolerated in a small, randomized, double-blind, controlled study.[19,31]

Clinical trials evaluating various formulations of magnesium for migraine prevention have yielded mixed results. CNS levels of magnesium are known to be significantly low during migraine attacks. Magnesium supplementation may be particularly effective for prevention of menstrual migraine and in migraine patients with aura.[19,31] Localized injections of botulinum toxin type A have been used for various conditions and pain syndromes, including migraine headache. However, no consistent, statistically significant benefits have been found with migraine. The American Academy of Neurology concludes that botulinum toxin is probably ineffective.[31,32] Further study is needed to confirm the clinical utility and comparative efficacy of these miscellaneous agents for the prophylactic management of migraine.

PHARMACOECONOMIC CONSIDERATIONS

Although migraine is widely recognized as a disease that exacts an enormous toll on the sufferer, the direct and indirect costs associated with migraine headache impose a substantial burden on society as well. The direct medical costs associated with clinic visits for headache and migraine diagnosis and treatment are substantial, exceeding $1 billion per year. Migraine also results in high use of

emergency rooms and urgent care centers.[1,3] Headache accounts for one third of all over-the-counter analgesic use in the United States, and gross sales from triptans alone total more than $1 billion per year. The indirect costs of the illness related to work absenteeism, decreased productivity, and impairment greatly exceed the direct cost of medical care.[3] Overall, the estimated lost productivity due to headache in the United States is $18 billion per year. The estimated indirect cost of migraine-specific related disability for American employers is approximately $13 billion each year.[3,19]

In 2004, only half of those surveyed with clear symptoms of migraine were diagnosed by a physician.[6] According to the American Migraine Prevalence and Prevention Study, although most episodic migraine sufferers take medications for their headaches, 21% used opioids or compounds containing barbiturates, and only 24% used a triptan.[6] Just 13% of this population were using medications specifically to prevent migraine, though 26% met criteria to be offered prophylaxis, and an additional 13% should be considered for treatment.[6] Because many migraineurs who receive inadequate care experience substantial levels of pain and disability, improvement in migraine diagnosis, care, and treatment potentially could result in lower direct and indirect costs of the disease.

Education of headache patients regarding required behavior changes and effective use of acute and prophylactic pharmacotherapy can be time-consuming, but it is also extremely cost-effective. Oversights can lead to decreased efficacy of medications resulting in repeat dosing and polypharmacy, decreased compliance, increased emergency visits, increased "doctor shopping," and, perhaps, increased use of expensive diagnostic procedures and inpatient services. Recent studies demonstrate that effective migraine treatment can reduce the functional disability and productivity loss associated with a migraine attack.[14,28] Patients with stratified care targeted to their needs had higher headache response rates, shorter disability times, less health service utilization, and less loss of productivity.[14]

SUMMARY

Acute and preventive pharmacotherapy for migraine should be individualized based on the individual patient response, tolerability of the available agents, and presence of comorbid conditions. Migraine management should be individualized on the basis of the patient's clinical presentation and medical history. Analgesics and NSAIDs can be considered the drugs of choice if effective for infrequent mild to moderate attacks. The triptans or dihydroergotamine can be used if initial therapies prove ineffective or as first-line therapy in moderate to severe migraine headache. Abortive therapy should be instituted early in the course of the attack to optimize efficacy and minimize migraine-related pain and disability. Preventive therapy should be considered in the setting of recurring migraines that produce significant disability, frequent attacks requiring symptomatic medication more than twice per week, symptomatic therapies that are ineffective, contraindicated, or produce serious side effects, and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury. Efficacy of a prescribed prophylactic regimen should be reassessed periodically. A prolonged headache-free interval could allow for gradual dosage reduction and discontinuation of therapy.

TENSION-TYPE HEADACHE

EPIDEMIOLOGY

Tension-type headache is the most common type of primary headache, with an estimated 1-year prevalence ranging from 31% to 86%.[4,33] Prevalence peaks in the fourth decade and is higher among women. The incidence decreases with age.[33,34] Although an estimated 60% of tension-type headache sufferers experience some degree of functional impairment during their attacks, less than 15% of sufferers seek medical attention, likely because most have infrequent attacks. Infrequent episodic tension-type headache (defined as fewer than one episode per month) is experienced by 64% of sufferers, while 22% have frequent episodic tension-type headache (episodes on 1–14 days per month). The prevalence of chronic tension-type headache (≥15 days per month, perhaps without recognizable episodes) is estimated at 0.9% to 2.2%.[4,33] Risk factors associated with a poor outcome in tension-type headache include coexisting migraine, sleep problems, not being married and the presence of chronic tension-type headache.[34]

PATHOPHYSIOLOGY

Although tension-type headache is the most common type of headache, it is the least studied of the primary headache disorders, and there is limited understanding of key pathophysiologic concepts.[8] Some evidence supports that migraine and tension-type headaches represent a continuum of headache severity with similarities in mechanisms and pathophysiology.[8] However, more recently, tension-type headache has been recognized as a distinct disorder. The mechanism of pain in chronic tension-type headache is thought to originate from myofascial factors and peripheral sensitization of nociceptors. Central mechanisms also are involved.[8,33] Mental stress, nonphysiologic motor stress, a local myofascial release of irritants or a combination of these may be the initiating stimulus. Following activation of supraspinal pain perception structures, a self-limiting headache results in most individuals owing to central modulation of the incoming peripheral stimuli. Chronic tension-type headache can evolve from episodic tension-type headache in predisposed individuals due to a change in central circuits and nociceptive processing along the brainstem reflex pathway and subsequent sensitization of the CNS.[8,33,34] It is likely that other pathophysiologic mechanisms also contribute to the development of tension-type headache.

CLINICAL PRESENTATION

Premonitory symptoms and aura are absent with tension-type headache. The pain usually is mild to moderate in intensity and often is described as a dull, nonpulsatile tightness or pressure.[2,12] Bilateral pain is most common, but the location can vary (frontal and temporal pain are most common; occipital and parietal regions also may be affected).[2] The pain is classically described as having a "hatband" pattern. Associated symptoms generally are absent, but mild photophobia or phonophobia may be reported. The disability associated with tension-type headache typically is minor in comparison with migraine headache, and routine physical activity does not affect headache severity.[2,4] Palpation of the pericranial or cervical muscles can reveal tender spots or localized nodules in some patients.[2] Tension-type headache is classified as either episodic (infrequent or frequent) or chronic based on the frequency and duration of the attacks.[2]

TREATMENT

Tension-Type Headaches

GENERAL APPROACH TO TREATMENT

The vast majority of episodic tension-type headache sufferers self-medicate with over-the-counter medications and do not consult a

healthcare professional. Although pharmacologic and nonpharmacologic treatments are available, simple analgesics and NSAIDs are the mainstay of acute therapy. Most agents used for tension-type headache have not been studied in controlled clinical trials.[35]

NONPHARMACOLOGIC THERAPY

Psychophysiologic therapy and physical therapy have been used in the management of tension-type headache. Behavioral therapies can consist of reassurance and counseling, stress management, relaxation training, and biofeedback. These therapies (alone or in combination) can result in a 35% to 50% reduction in headache activity.[36] Evidence supporting physical therapeutic options, such as heat or cold packs, ultrasound, electrical nerve stimulation, stretching, exercise, massage, acupuncture, manipulations, ergonomic instruction, and trigger point injections or occipital nerve blocks, is somewhat inconsistent. However, individual patients may benefit from selected modalities in reducing the frequency of tension-type headache or during an acute episode.[35]

PHARMACOLOGIC THERAPY

Simple analgesics (alone or in combination with caffeine) and NSAIDs are effective for the acute treatment of most mild to moderate tension-type headaches. Acetaminophen, aspirin, ibuprofen, naproxen, ketoprofen, and ketorolac have demonstrated efficacy in placebo-controlled and comparative studies.[35] Failure of over-the-counter agents can warrant therapy with prescription drugs. High-dose NSAIDs and the combination of aspirin or acetaminophen with butalbital or, rarely, codeine are effective options. Use of butalbital and codeine combinations should be avoided when possible owing to the high potential for overuse and dependency. As with migraine headache, acute medication should be taken for episodic tension-type headache no more than 9 days per month to prevent the development of chronic tension-type headache.[35] There is no evidence to support the efficacy of muscle relaxants in the management of episodic tension-type headache.[35] Preventive treatment is appropriate for most patients with chronic tension-type headache and should be considered in those with frequent episodic tension-type headache if frequency (>2 per week), duration (>3–4 hours), or severity results in medication overuse or substantial disability.[36] The principles of preventive treatment for tension-type headache are similar to those for migraine headache. TCAs are prescribed most often for prophylaxis, but other drugs also can be selected after consideration of comorbid medical conditions and respective side-effect profiles. SSRIs are not effective in patients with tension-type headache who do not have depression, however, limited studies support the use of the SNRIs mirtazapine and venlafaxine.[34,36] Injection of botulinum toxin into pericranial muscles has demonstrated inconsistent efficacy in the prophylaxis of tension-type headache and because of this, it is not recommended for use.[32,36]

CLUSTER HEADACHE

EPIDEMIOLOGY

Cluster headache, the most severe of the primary headache disorders, is characterized by attacks of severe, unilateral head pain that occur in series lasting for weeks or months (i.e., cluster periods) separated by remission periods usually lasting months or years.[2,37] Cluster headaches can be episodic or chronic.[2] Cluster headache is relatively uncommon among the primary headache disorders, but the exact prevalence is uncertain. The prevalence varies from 56 to 401 per 100,000.[37] Men are more likely than women to have cluster headache, and onset generally occurs after age 20.[37] Recent genetic epidemiological surveys support a predisposition for cluster headache can exist in certain families.[37,38]

PATHOPHYSIOLOGY

The etiologic and pathophysiologic mechanisms of cluster headache are not completely understood. The cyclic nature of attacks implicates a pathogenesis of hypothalamic dysfunction with resulting alterations in circadian rhythms.[8] Hypothalamus-regulated changes in cortisol, prolactin, testosterone, growth hormone, leuteinizing hormone, endorphin, and melatonin have been found during periods of cluster headache attack.[8,41] Neuroimaging studies performed during acute cluster headache attacks have demonstrated activation of the ipsilateral hypothalamic gray area, implicating the thalamus as a cluster generator.[8] Significant cranial autonomic activation occurs ipsilateral to the pain, through the same pathways that are activated during migraine.[8]

CLINICAL PRESENTATION

Attacks occur in cluster periods lasting 2 weeks to 3 months in most patients, followed by long pain-free intervals.[2,39] Periods of remission average 2 years in length but have been reported to be from 2 months to 20 years in duration. Approximately 10% of patients have chronic symptoms with attacks recurring for over 1 year without remission or with remission periods of less than 1 month.[2,39] Cluster headache attacks occur commonly at night and more commonly in the spring and fall.[39] Attacks occur suddenly, with pain peaking quickly after onset and generally lasting 15 to 180 minutes.[2] Auras are not present with cluster headaches. The pain is excruciating, penetrating, and of a boring intensity in orbital, supraorbital, and temporal unilateral locations.[2,39,40] The headache can be accompanied by conjunctival injection, lacrimation, nasal stuffiness, rhinorrhea, eyelid edema, facial sweating, miosis/ptosis, and restlessness or agitation. During the cluster period, attacks occur from once every other day to eight times per day.[2,39,40] Whereas migraine patients retreat to a quiet dark room, cluster headache patients generally sit and rock or pace about the room clutching their head.[39] There is a male preponderance in cluster headache, especially in the chronic form, and lifestyle habits such as smoking and consumption of alcohol or coffee are common.[40] Specific diagnostic criteria for cluster headaches are provided within the IHS classification system.[2]

TREATMENT

Cluster Headaches

As in migraine, therapy for cluster headaches involves both abortive and prophylactic therapy. Abortive therapy is directed at managing the acute attack. Prophylactic therapies are started early in the cluster period in an attempt to induce remission. Patients with chronic cluster headache can require prophylactic medications indefinitely.

ABORTIVE THERAPY

Oxygen

The standard acute treatment of cluster headache is inhalation of 100% oxygen by nonbreather facial mask at a rate of 7 to 10 L/min for 15 to 30 minutes.[41] Repeat administration can be necessary because of recurrence, as oxygen appears to merely delay, rather than abort, the attack in some patients.[41] No side effects have been reported with the use of oxygen, but caution should be used for those who smoke or have chronic obstructive pulmonary disease.

Ergotamine Derivatives

All forms of ergotamine have been used in cluster headaches, although no controlled clinical trials support their use.[41,42] In clinical use, intravenous dihydroergotamine results in the quickest response, and repeated administration for 3 to 7 days can break the cycle of frequent attacks.[41] Ergotamine tartrate also has provided effective relief of cluster headache attacks when administered sublingually or rectally, but the pharmacokinetics of these preparations frequently limit their clinical utility.[41] Dosing guidelines are similar to those for migraine headache therapy.

Triptans

The quick onset of subcutaneous and intranasal triptans make them safe and effective abortive agents for cluster headaches. Subcutaneous sumatriptan (6 mg) is the most effective agent. Nasal sprays are less effective but may be better tolerated in some patients. Adverse events reported in cluster headache patients are similar to those seen in migraineurs. Orally administered triptans have limited use in cluster attacks because of their relatively slow onset of action; oral zolmitriptan (10 mg), however, was beneficial in patients with episodic cluster headache with 60% experiencing mild or no pain at 30 minutes.[39,41,42]

PROPHYLACTIC THERAPY

Verapamil

Verapamil, the preferred calcium channel blocker for the prevention of cluster headaches, is effective in approximately 70% of patients.[41,42] The beneficial effects of verapamil often appear after 1 week of therapy. A typical suggested dosage range is from 360 to 720 mg/day, with some patients requiring up to 1,200 mg/day.[41,43]

Lithium

Lithium carbonate is effective for episodic and chronic cluster headache attacks and can be used in combination with verapamil. A positive response is seen in up to 78% of patients with chronic cluster headache, and in up to 63% of patients with episodic cluster headache.[41] The usual dose is 600 to 1,200 mg/day, with a suggested starting dose of 300 mg twice daily. Optimal plasma lithium levels for prevention of cluster headache have not been established, but trough values should not be more than 1.0 mEq/L (mmol/L).[41]

Initial side effects are mild and include tremor, lethargy, nausea, diarrhea, and abdominal discomfort. Thyroid and renal function must be monitored during lithium therapy. Lithium should be administered with caution to patients with significant renal or cardiovascular disease, dehydration, pregnancy, or concomitant diuretic or NSAID use.[39,41]

Ergotamine

Ergotamine, once commonly used, can be efficacious for prophylactic as well as abortive therapy of cluster headaches. A 2-mg bedtime dose is often beneficial for the prevention of nocturnal headache attacks. Daily use of 1 to 2 mg ergotamine alone or in combination with verapamil or lithium can provide effective headache prophylaxis in patients refractory to other agents with little risk of ergotism or rebound headache.[39,41] Although there is more literature on methysergide, a serotonergic agent related to ergotamine, as a prophylactic treatment for cluster headache, this agent is no longer available.[39]

Corticosteroids

Corticosteroids are useful for inducing remission.[39,41] Therapy is initiated with 40 to 60 mg/day prednisone and tapered over approximately 3 weeks. Relief appears within 1 to 2 days of initiating therapy. To avoid steroid-induced complications, long-term use is not recommended. Headaches can recur when therapy is tapered or discontinued.

Miscellaneous Agents

Other therapies that have been used in the acute management of cluster headache include intranasal lidocaine, hyperbaric oxygen, and subcutaneous octreotide. Limited studies or case reports also support the use of divalproex sodium, topiramate, gabapentin, intranasal civamide, intranasal capsaicin, tizanidine, baclofen, melatonin, transdermal clonidine, leuprolide, and intramuscular botulinum toxin for cluster prophylaxis. Neurosurgical intervention can be necessary for patients with chronic cluster headache that is resistant to all medical therapies.[41,42]

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored for frequency, intensity, and duration of headaches, as well as any change in the headache pattern. To this end, migraineurs should be encouraged to keep a headache diary to document the frequency, severity, and duration of migraine attacks, as well as response to medication and potential trigger factors. Careful monitoring is essential to initiate the most appropriate pharmacotherapy, document therapeutic successes and failures, identify medication contraindications, and prevent or minimize adverse events. Patients using acute therapies should be monitored for frequency of use of prescription and over-the-counter medications to identify potential medication-misuse headache. Patient counseling is necessary to allow for proper medication use (e.g., self-injection with sumatriptan), to encourage early use of medications in the headache cycle, and to enhance patient compliance. Strict adherence to dosing guidelines should be stressed to minimize potential toxicity. Patterns of abortive medication use can be documented to establish the need for prophylactic therapy. Prophylactic therapies also should be monitored closely for adverse reactions, abortive therapy needs, adequate dosing, and compliance. Consultation with other healthcare practitioners should be encouraged when changes in headache patterns or medication use occur.

CONCLUSIONS

Although headache disorders such as migraine and cluster headaches appear to occur as a result of neuronal dysfunction, the precise etiology and nature of the dysfunction are unknown. Serotonergic neurotransmission and the trigeminovascular system appear to play important roles. A careful patient workup, including patient history, physical examination, and appropriate laboratory tests, should identify most headache patients with major disease. A variety of strategies can be helpful for managing migraine, tension-type, and cluster headaches. Management of primary headache disorders is directed at suppressing acute attacks and preventing recurrences. Continuing research will better define pathophysiologic mechanisms and aid the search for less toxic and more efficacious pharmacologic agents.

ABBREVIATIONS

5-HT: serotonin, 5-hydroxytryptamine

CGRP: calcitonin gene–related peptide

CNS: central nervous system

SECTION 7
PSYCHIATRIC DISORDERS

CHAPTER 71

Evaluation of Psychiatric Illness

MARK E. SCHNEIDERHAN, LEIGH ANNE NELSON, AND STUART MUNRO

KEY CONCEPTS

1. Patients with psychiatric conditions are treated in all healthcare settings. All clinicians need to develop basic skills in psychiatric assessment to provide the best care for their patients.
2. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* is the most widely accepted diagnostic reference. It, along with the *American Psychiatric Association Practice Guidelines for the Psychiatric Evaluation of Adults,* provides the clinician a standardized approach for the initial assessment and follow-up of patients with mental illness.
3. At times, patients suffering from mental illness are challenging to assess, as their condition can prevent them from full cooperation. A range of strategies can be used to gather the needed information while maintaining the safety and comfort of both patient and clinician.
4. A thorough medication history to identify all medications currently taken, as well as those previously taken, is a cornerstone of effective patient management. In addition, it must be determined whether there was an adequate trial (dose and duration) of current and prior medications for psychiatric illnesses.
5. A baseline mental status examination, along with a specific target symptom list, is a critical tool in monitoring response to treatment.
6. Several papers have been published in recent years recommending specific physical assessment and laboratory tests needed for the evaluation of patients with psychiatric conditions. Except for patients taking antipsychotics, no single standard exists, and testing is individualized based on the patient's age, medical history, current physical health, and current medication use; and in consideration of the most recent expert opinion.
7. Baseline and follow-up monitoring for metabolic disturbances should be instituted for all patients taking antipsychotics.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Patients with mental illnesses are treated by clinicians from many disciplines and in all settings of healthcare, and they often receive the bulk of their care from nonpsychiatrists. Hence the need for good psychiatric assessment skills is not limited to mental health specialists. Along with traditional assessments used across all medical specialties (e.g., laboratory tests, medical history, and physical examination), psychiatric practitioners use additional strategies to manage their patients that are perhaps less objective in nature and less familiar to nonpsychiatric practitioners. This chapter provides a basic overview of appropriate assessment techniques used by clinicians to develop an individualized treatment plan for psychiatric patients. Readers needing greater depth than the materials provided in this chapter are referred to other sources.[1–6]

OVERVIEW OF THE DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS

2 The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* is the most widely accepted and most important diagnostic reference used in the care of the mentally ill. It provides a common language for practitioners to describe and diagnose psychiatric disorders.[7] Common language is essential because there is considerable overlap of symptoms across many diagnoses. The *Diagnostic and Statistical Manual of Mental Disorders, First Edition (DSM-I)* was introduced in 1952 and was the first manual on mental disorders to contain a description of diagnostic categories. The most recent edition, *DSM-IV-TR*, was released in 2000 and uses essentially the same diagnostic criteria sets as the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*.[7] Its purpose is to correct factual errors in *DSM-IV* and update the text sections (e.g., associated features, prevalence, and differential diagnosis) with more contemporary data. A more

significant rewriting of diagnostic criteria and introduction of new diagnoses will appear in *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-V*), which probably will not be available until May 2015.[7] The *DSM-IV-TR* contains many components that provide a comprehensive understanding of specific mental illnesses and assist in making an accurate diagnosis. For example, the multiaxial patient evaluation ensures that most factors that could contribute to, or complicate, the condition are considered during a patient assessment and throughout treatment planning. Axis I lists the principal psychiatric disorder (e.g., schizophrenia, etc), developmental disorders, or provisional diagnoses present in the patient. Mental retardation and personality disorders (e.g., antisocial, borderline, etc.) are listed on Axis II. Axis III lists existing physical disorders or conditions. Axis IV lists the severity of psychosocial stressors that might have contributed to a new or recurrent mental disorder or exacerbation of an existing condition. Stressors are rated on a scale of 1 (none) to 6 (catastrophic) and can be acute (lasting less than 6 months) or enduring (lasting longer than 6 months). Examples of stressors include difficulties with interpersonal relationships, parenting, occupation, living circumstances, finances, the legal system, and health. Axis V describes the global assessment of functioning (GAF), rated on a scale from 1 (persistent danger to self or others) to 90 (minimal or absent symptoms). A GAF rating is made based on the current level of functioning and can be used to describe the highest level of functioning achieved prior to the current evaluation. By documenting the baseline level of functioning, the GAF helps evaluate progress toward a patient's therapeutic goals.

DSM-IV-TR provides general information on all mental disorders recognized by the American Psychiatric Association (APA) and includes age of onset, clinical course, complications, predisposing factors, prevalence, and differential diagnoses. The specific diagnostic criteria for each mental illness and the number of symptoms required to establish a diagnosis are also listed. The *DSM-IV-TR* also includes decision trees for differential diagnosis and a glossary of technical terms. The *Clinical Interview Using DSM-IV* is a companion publication that provides extensive information on interviewing techniques helpful in establishing a specific *DSM-IV* diagnosis.[7]

Additional information besides the *DSM-IV-TR* diagnosis is required before a comprehensive treatment plan can be developed. The *American Psychiatric Association Practice Guidelines for Psychiatric Evaluation of Adults* (2nd edition) includes a full discussion of the domains needed for a thorough clinical evaluation. It also discusses issues of privacy, appropriate setting for assessment, and evaluations in special populations.[5]

In summary, the *DSM-IV-TR* and the APA practice guidelines allow clinicians to evaluate patients in a systematic manner, thereby creating better treatment plans and a more consistent evaluation of response.

THE CLINICAL INTERVIEW

The interview should be conducted in a quiet, nonstimulating, and comfortable area where the patient and the interviewer feel at ease.[6] The setting should be appropriate to the patient's level of acuity and the potential for risk to the patient and clinician. The interviewer should introduce himself or herself and explain what is about to happen in order to establish a trusting relationship. Generally, open-ended questions come first, followed by questions focused on more specific or personal data. Open-ended questions allow the patient to provide descriptions and other information in his or her own words. Even though more specific questions may then be necessary to fill in the gaps, beginning in this manner minimizes the risk of "leading" the patient. Patients can respond to specific questions and "yes" or "no" questions with answers they think the interviewer wants to hear. The interviewer must be nonjudgmental about the information offered by the patient to develop trust and rapport and to ensure completeness and accuracy of the information. Whether a clinician takes notes or just listens during the interview is an individual decision, with the primary considerations being to make an accurate record of the content of the examination and assuring that the patient is comfortable with the note taking. Table 71–1 provides examples of questions useful for gathering information during the completion of the clinical interview.

TABLE 71-1 Examples of Interview Questions for Assessing Mental Illnesses

Mania
1. Do your thoughts go faster than you can say them?
2. Have you noticed a change in the amount of sleep that you require?
3. Have you spent a lot of money lately, and what did you spend it on?
4. Do you have a lot of extra energy?

(To assess hallucinations and delusions, see Schizophrenia section below.)

Depression
Do you cry without any reason?
Do you still enjoy the same hobbies/activities that you once did?
Has your weight changed recently?
Have you had changes in your energy level recently?
Do you have any guilty feelings?
Do you find it difficult to remember phone numbers, names of friends, appointments, and so on?

(To assess sleep and suicidal potential, see Sleep and Suicide sections below.)

Schizophrenia
Delusions
1. Do you feel that people plot against you?
2. Do you ever feel that you are watched or spied on?
3. Do you have any special abilities?
4. Does anyone ever try to mess with you or bother you?
5. Do others read your thoughts?

Hallucinations
1. Does the TV/radio ever tell you things?
2. Do you hear voices that other people don't hear?
3. What do they say? How many voices?
4. How often do they bother you?
5. Do the voices ever tell you to hurt yourself or someone else?
6. Have you ever heard your name called when there is no one there?
7. Have you ever seen anything strange that you can't explain?
8. Do you ever see things that bother you and no one else?
9. Do you want to act on what the voices say?

Thought broadcasting/insertion
1. If I stood by you, could I hear your thoughts?
2. Does your head ever act like a radio?
3. Do you feel that others can put thoughts in your head?

Insight
1. What reasons did your family give you for coming here?
2. What brought you here?
3. Do you consider yourself in need of help?
4. What does your medication do for you?

Sleep
1. Tell me about your sleep.
2. How many hours do you sleep each night at present?
3. How many hours do you usually sleep at night?
4. Do you sleep all through the night?
5. Is there a reason for your waking up?
6. Do you have trouble falling asleep?
7. How do you feel when you wake up?

Suicide potential
1. Do you feel your life is not worth living?
2. Do you ever think of hurting yourself?
3. Do you see things improving in the future?
4. Do you think you will try to hurt yourself now?
5. How would you do it?
6. Do you have the means to hurt yourself?

THE CHALLENGING PATIENT

3 Patient assessments can be challenging when symptoms of the condition prevent effective engagement with the clinician. Excited patients may exhibit speech that is rapid and unorganized; whereas, depressed patients may respond with few words. Patients in the manic phases of bipolar disorder may not pause as they speak (pressured speech), making it difficult for the interviewer to interject. In all cases, the interviewer can regain control by politely redirecting the patient back toward the question. Psychotic patients may be paranoid and appear guarded or frightened by the questions. The best approach is to remain calm and respectful, use shorter or closed-ended questions, and seek only essential information until the patient is less paranoid. Patients can become agitated and occasionally violent. Often violence is preceded by increased psychomotor agitation as evidenced by pacing, speaking in a loud voice, or gripping the arms of the chair. When there is concern about safety, the interviewer should avoid any behavior that could be misconstrued as threatening, such as touching or unnecessary staring, and interview the patient in the presence of another healthcare provider. Both the patient and interviewer should have equal access to leave the room if either becomes too uncomfortable. If a patient becomes threatening to the interviewer, the interviewer should not hesitate to leave the room and call for help. If a patient describes suicidal thoughts, he or she should be further assessed using the questions outlined in Table 71–1, and depending on the results of further assessment should be directed to the appropriate type of care, including hospitalization for patients at immediate risk of harming themselves. A suicidal patient should never be left alone. Asking a patient about suicidal thoughts will not increase the risk. The risk is greater if these questions are never asked or signs of distress are ignored. Before any conclusions are made about a patient interview, the impact of culture on the patient's presentation should be considered. Something that sounds delusional in Western culture can be the norm in others. If a clinician is unclear whether culture of origin accounts for some of the patient's symptoms, he or she should consult with a family member or someone else familiar with the patient's culture of origin.

PSYCHIATRIC HISTORY

Both the patient's and the patient's family history of mental illness provide important information when formulating a diagnosis and treatment plan. Information should include the current and previous psychiatric diagnoses, the clinical presentation of each illness, time frame between episodes, level of functioning between episodes, length of each episode, total duration of illness, and treatment given during each episode as well as response to those treatments. Baseline functioning or the highest level of functioning achieved in the past few years is important because it helps to define a treatment goal. Information on the history of the current episode and reasons for presenting to the clinician also should be gathered. A family history should include a medication history of the immediate relatives because a family member's response to a given medication might predict an individual patient's response to that same medication.

SOCIAL HISTORY

A social history should include educational and occupational background, religion, marital status, substance-use patterns including tobacco, alcohol, and caffeine, and current living situation. By understanding a patient's living environment and social situation, strategies to foster treatment adherence, reduce stress, and increase social support can be developed. To probe this area initially, the clinician can ask patients to describe their social support network. This can be followed by more specific questions such as "To whom are you closest?" or "In whom do you confide?"

MEDICATION HISTORY

4 A thorough medication history is one of the most important contributions a clinician can make to treatment planning. The history should include medications for both psychiatric and medical conditions. It should list all medications taken by the patient, and report on how each was tolerated and the nature of the response to that drug or combination of drugs. All allergies must be noted. Because most psychiatric medications have a delay in the onset of effect, it is important to determine whether an adequate trial (dose and duration) was provided before the patient was deemed "nonresponsive" to that drug. If a patient has a history of nonadherence, specific causes such as cost, complicated dosing schedules, lack of insight, and adverse effects should be investigated.

MENTAL STATUS EXAMINATION

5 The mental status examination (MSE) is a key patient assessment tool in psychiatry and is analogous to the physical examination in medicine. The MSE is completed through a direct patient interview and results in a description of current behavior, thoughts, perceptions, and functioning. The MSE provides an objective evaluation used in diagnosis, assessment of the course of the illness, and response to treatment. It is combined with other components of the patient workup (history of present illness, physical examination, appropriate laboratory tests, and medical and psychiatric history) to give a full picture of the presenting problem and factors contributing to the illness. The MSE has several components.[5–7]

Appearance and Attitude Toward Examiner

The appearance of the patient throughout the interview should be noted, including age, dress, grooming and hygiene, use of cosmetics, and facial expressions. A description of appearance also should include unusual physical characteristics and the general state of physical health. The interviewer should note whether the patient is cooperative, mute, hostile, paranoid, guarded, or withdrawn.

Activity

Motor activity may be excessive or diminished. Overactivity can include pacing; hand wringing; picking at clothing, skin, or hair; inability to sit still during the interview; and excessive hand gestures. Underactive patients move less than expected. Patients with rigid posture, an absence of movement, and failure to communicate may be catatonic, paranoid, or experiencing medication-induced adverse effects.

Speech and Language

The quantity, flow, and speed of speech and the amount of eye contact should be noted. The appropriateness and degree of eye contact varies significantly between cultures, and before poor eye contact is interpreted, the patient's cultural background should be considered. Speech should be assessed as to whether it proceeds logically in a goal-directed manner or whether the content is vague and poorly organized. Abnormal speech characteristics include thought blocking, whereby the person suddenly stops speaking without any obvious reason. Thought blocking usually occurs when a hallucination or delusion intrudes into the person's thinking or when upsetting issues are discussed. Circumstantial speech lacks a clear direction because of excess unnecessary information, but the circumstantial patient eventually will make his or her point. In tangential speech, however, the ultimate point is never made. *Perseveration* is repetition of an

original answer to subsequent questions. *Flight of ideas* is overproductive, rapid speech during which the patient jumps rapidly from one idea to the next. *Mutism* is identified when the patient does not respond even though he or she is aware of the discussion.

Affect and Mood

Affect describes the patient's current emotional tone, as expressed through facial expression, body posture, and tone of voice, all of which can be objectively observed by the clinician. Mood describes feelings, which are subjectively reported by the patient. Change in facial expression and the presence of tears, flushing, sweating, or tremors should be noted. Affect can be described further by its range, appropriateness, intensity, and stability. For example, in schizophrenia or depression, the affect can be *flat*, whereby no change in expression occurs throughout the interview. In contrast, during a manic episode, the affect is very intense and often *excited*. *Blunted affect* denotes that the range of emotional expression is reduced, but not absent. An example of *inappropriate affect* is when a patient laughs in a situation that would be expected to produce sadness. A rapidly shifting affect from one extreme to the other is described as *labile*.

Thought and Perceptual Disturbances

A variety of thought disturbances can occur in mental illness. Many of these disturbances generally indicate the presence of psychosis or impaired reality testing. *Delusions* are fixed, false beliefs that are not based in reality or consistent with the patient's religion or culture. Delusions can be paranoid, somatic, or grandiose in nature. Delusions are often unshakable, and although the clinician can challenge the delusional thinking, one should not attempt to talk a patient out of a delusion. *Thought broadcasting* is the belief that one's thoughts are audible to others. *Hallucinations* are false sensory impressions or perceptions that occur in the absence of an external stimulus. Hallucinations can be auditory, visual, olfactory, tactile, or gustatory and can be continuous or intermittent. In contrast, *illusions* are visual misperceptions involving a misinterpretation of a real sensory stimulus. For example, a person who initially misperceives a curtain blown by the wind to be an intruder has experienced an illusion. This phenomenon does not always indicate a psychiatric illness and can be seen in persons without mental illness. Not all thought disturbances are indicative of psychosis. For example, the couplet of obsessions and compulsions can indicate the presence of obsessive-compulsive disorder, which is not considered to be a psychotic disorder. *Obsessions* are unwanted thoughts or ideas that intrude into a person's thinking. *Compulsions* are actions performed in response to the obsessions or to control anxiety associated with the obsession.

Evaluation of Cognition

The mental status exam assesses sensorium, attention, concentration, memory, and higher cognitive functions such as orientation and abstraction. The clinician should document whether the patient has received medications with sedative properties, because the outcome of the examination can be altered if central nervous system depressants were recently taken.

Sensorium, or level of consciousness, refers to the alertness of the patient, and if he or she is not fully alert, the amount of stimulation needed to awaken the patient. Attention and concentration can be assessed using serial subtraction by 7s ("serial 7s") or 3s, or by having a patient spell a five-letter word backward. General intelligence can be assessed loosely by asking factual information about current news items, recent presidents, or popular television shows or sporting events. *Memory* is the ability to recall past experiences and is classified as sensory stores (which lasts seconds), short-term memory (the ability to recall newly acquired information after several minutes), working memory (i.e., immediate application of visual or auditory instructions), and long-term or remote memory (historical facts). Orientation to time, place, person, and situation assesses sensory stores and short-term memory. Asking a patient to recall three objects 5 minutes after they are learned is the definitive test for short-term memory. Deficits in short-term memory may be seen in depression and anxiety, but this finding is the hallmark feature of dementia. Asking the patient to do a certain task (e.g., pick up a pen with his or her right hand and then fold a piece of paper and pass it to the examiner) can assess the patient's working memory. Patients with cognitive deficits, such as those seen in dementias and schizophrenia, can exhibit deficits in working memory. Remote memory is assessed by asking patients to recall old facts about their lives, such as where they were born or where they went to school. Remote memory usually remains intact the longest in patients with intellectual decline, whereas the ability to create new memories is generally the first sign of a memory deficit. *Abstraction* is the ability to interpret information such as a proverb ("People in glass houses shouldn't throw stones") or identify similarities or differences between words (e.g., apple and orange). Abstraction is influenced by education, cultures and linguistic fluency; thus inability to abstract is not always a sign of a psychiatric disorder. Persons with schizophrenia often provide *concrete* (literal or superficial interpretations) or *bizarre* responses to probes of abstraction.

Insight and Judgment

Insight refers to patient awareness that he or she has a mental illness and the impact of that illness on his or her life. Patients typically demonstrate a lack of insight when they are psychotic. Patients with *poor* insight are often nonadherent with prescribed medications. Judgment is the ability to make decisions appropriate to the situation and can be impaired in a variety of mental illnesses. Judgment can be assessed by asking patients how they would handle either their current or a hypothetical situation. Both insight and judgment can be fluid. For example, intoxicated patients can demonstrate *poor* insight and judgment only to improve over several hours as their blood alcohol concentration decreases.

PHYSICAL EXAMINATION AND LABORATORY ASSESSMENT

There is no consensus about specific laboratory tests for diagnosing or evaluating mental illness.[2,5] The identification of biologic markers (e.g., pharmacogenomics) as diagnostic tools, predictors, or indicators of drug response is of great interest but currently of limited clinical usefulness. The most promising was the dexamethasone suppression test, proposed to be a marker for endogenous melancholic depression. However, its lack of sensitivity and specificity has limited its usefulness as a routine screening tool during a workup for depression.[2] Although there are no tests to definitively indicate that a patient has a specific mental illness (e.g., schizophrenia or bipolar disorder), laboratory tests are important to clarify the etiology of presenting symptoms.

Patients who present with psychiatric symptoms need a careful medical assessment because of overlapping symptoms.[1-3,6] A complete physical examination, along with a detailed medical and medication history, vital signs, weight and body mass index, a pregnancy test when indicated, and routine blood chemistry are commonly part of the workup of persons with mental illness. In most cases, a physical examination should be chaperoned.

Both medical illnesses and medications can cause the same psychiatric symptoms. The rapidity of onset of psychiatric symptoms

is an important clue that a medical cause may be present. Most chronic mental illnesses have a prodromal period, whereas medically based psychiatric symptoms generally have a more rapid onset of symptoms. Patients older than 40 years of age at first presentation are more likely to have a medical cause for their psychiatric symptoms because major psychiatric illnesses such as schizophrenia and bipolar disorder usually first present in adolescence or early adulthood. Family history can provide additional clues. Patients with fluctuating levels of consciousness, disorientation, memory impairment, or visual, tactile, or olfactory hallucinations are more likely to have a medical basis for their presentation.

Patients with psychiatric illnesses, especially depression and anxiety disorders, often present with only physical complaints, leading to inappropriate care for medical problems that are not present or as serious as they may appear, while the root cause is ignored. In contrast, patients with severe persistent mental illness (e.g., schizophrenia) have increased risks for cardiovascular disease and are less likely to receive the same level of primary medical care compared to patients without mental illness.[8–10] Barriers to medical care include patient paranoia, ambivalence, and disorganization accounting for missed appointments; stigma toward mental illness; and poor communication between primary care and psychiatric clinicians.[11] Antipsychotic therapy can also cause or exacerbate medical conditions, such as diabetes mellitus, hyperlipidemia, or cardiac arrhythmias, necessitating an initial assessment and ongoing monitoring for these conditions while continuing treatment.[12,13]

6 General laboratory screening is useful for ruling out medical causes of psychiatric illnesses and medication monitoring. Urine drug screens and blood alcohol tests play an important role in identifying the contribution of substances of abuse to the presenting symptoms. Additional testing can include an electroencephalogram to evaluate for the presence of seizure activity or other neurologic conditions, computed tomography or magnetic resonance imaging to detect structural abnormalities, sedimentation rate and antinuclear antibodies for autoimmune disorders, a human immunodeficiency virus test, thyroid function tests, and vitamin B_{12} and folate concentrations for anemias.[2] Laboratory tests should be individualized to the age, medical/medication history, cooperativeness, and physical health of the patient, but extensive testing is usually unnecessary and not cost-effective.

Clinicians also use diagnostic tests to evaluate the relative safety of specific medications such as pregnancy monitoring with divalproex, renal status when using lithium, or an electrocardiogram when using a tricyclic antidepressant such as amitriptyline. Baseline information is often needed to help document future adverse effects from medications (e.g., lithium-induced hypothyroidism, clozapine-induced leukopenia, antipsychotic-induced diabetes mellitus). Serum concentration monitoring is recommended for medications with a narrow therapeutic index such as lithium, divalproex, and carbamazepine. Serum concentration monitoring can also be useful for assessing medication adherence when there is inadequate response. With the exceptions of lithium, divalproex, and clozapine, there is minimal data to support obtaining serum concentrations for optimizing medication efficacy in psychiatric disorders.

7 The 2004 expert consensus recommends that patients starting on newer antipsychotic agents should be screened for symptoms of metabolic syndrome including body weight (baseline, weeks 4, 8, and 12, then every 3 months (12 weeks), then annually), waist and hip measurements (baseline and annually), blood pressures (baseline, week 12, and annually), and fasting serum lipids and glucose (if possible at baseline, week 12, and annually for high-risk patients).[12–14] In 2007, it was reported that over 50% of patients on antipsychotics were not being monitored for diabetes and dyslipidemia.[15] Glucose and lipid monitoring continues to be underutilized for patients taking antipsychotics. Although fasting serum results are preferred over random serum or capillary blood specimens, this should not be a barrier to adequate monitoring.[16] The clinician can employ random glucose, high-density lipoprotein cholesterol levels, or glycosylated hemoglobin A_{1c} if there is difficulty obtaining fasting serum levels.[13,15]

In summary, a range of assessments aid the clinician in making problem-focused workups to verify diagnoses and identifying underlying or potential drug-related problems[17] The MSE is the cornerstone of the psychiatric workup, although selective medical tests, a good medical, psychiatric, and medication history, and a thorough physical examination are also important.

PSYCHIATRIC RATING SCALES

Psychiatric rating scales are useful tools to provide an objective way of measuring subjective data (e.g., feelings, thoughts, and perceptions) and to screen or diagnose specific disorders. As there are so many types of scales to choose from, the clinician rater needs training and experience to select and use the most appropriate scale. Rating scales are used in a variety of settings, including research and patient care, and can serve an administrative purpose such as quality control.[4]

Drawbacks to the more frequent use of clinician-rated scales include the substantial time commitment for staff to administer the tests and the inability of some patients to tolerate these interviews, especially patients who are severely paranoid or agitated. In addition, repeated ratings are usually necessary to objectively describe longitudinal changes over a defined treatment period as opposed to a snapshot of a complex clinical situation.

Some rating scales are self-administered (patient-rated) and do not require a staff member to collect the data; thus they require minimal resources to administer and can provide valuable information, although some patients may be unable to self-administer a questionnaire for a variety of reasons, including limited literacy and severity of symptoms.

In contrast to symptom-based rating scales (e.g., Positive and Negative Syndrome Scale or Hamilton Depression scale), global rating scales, such as the Clinical Global Impression scale, assess the overall severity of illness based on a rater's clinical experience.[18–20] In general, these rating scales measure the presence or severity of symptoms and can assist in the diagnostic formulation.

Rating scales are also available to measure adverse side effects from psychiatric medications. Specific adverse side-effect measures can be used for specific categories of medications. Table 71–2 provides a summary of the most common rating scales used to assess and quantify the presence and severity of adverse effects.[21]

Sensitivity, specificity, reliability, and validity are important considerations when selecting a rating scale. *Sensitivity* refers to a test's ability to detect a symptom or illness, given that the symptom or illness is present. *Specificity* refers to a test's ability to determine that a symptom or illness is absent given that the person does not have the illness.

Reliability is the extent to which the score on the scale reflects the hypothetical "true" score and how much interference occurs from outside influences.[22] Reliability is reported by the correlation coefficient, which represents a chance correlation (zero) or perfect correlation (1). Rating scales with correlation coefficients of less than 0.7 are usually considered unreliable for clinical studies. Interrater reliability—agreement in rating scores among clinician raters—is important to achieve when multiple clinicians rate the same patient or population. Interrater reliability is established by having all raters independently rate individual patients at the same time to determine the correlation of their scores.

TABLE 71-2 Adverse Effects Measures

Rating Scale	Type	Scoring	Comments
Systematic Assessment for Treatment of Emergent Events–General Inquiry (SAFTEE-GI)	Structured interview and global assessment	Summary scores of number of events, average severity, and impairment	5–10 minutes to complete. Baseline and weekly evaluations. Easy to administer. The specific reported information might be more useful than an overall summary score
MED Watch	Global assessment	No scoring involved	Minutes to complete. The one-page form requires a narrative description of the problem or adverse reaction. Online submission: *www.fda.gov/medwatch/*
Abnormal Involuntary Movement Scale (AIMS)	Tardive dyskinesia (TD) assessment	12-item, 5-point severity scale. Items 1–4 orofacial movement; 5–7 extremity and truncal movement; 8-10 global severity; 11 and 12 problems with teeth or dentures (yes or no)	5–10 minutes to complete. Most commonly used. Diagnostic criteria: at least 3 months of antipsychotic treatment. Mild severity score (2) in two discrete areas or moderate severity (3) in one area (e.g., orofacial) indicates TD. Tremor is not counted
Dyskinesia Identification System: Condensed User Scale (DISCUS)	Tardive dyskinesia assessment	15-item, 5-point severity scale. Items 1, 2 face; 3 eyes; 4, 5 oral; 6–9 lingual; 10, 11 head/neck/trunk; 12, 13 upper limb; 14, 15 lower limb	5–10 minutes to complete. More descriptive criteria for scoring severity than the AIMS. Scoring based on three dimensions: frequency, detectability, and intensity. Tremor is not counted
Rating Scale for Extrapyramidal Side Effects (Simpson-Angus EPS Scale)	Drug-induced Parkinson and dystonia assessments	10-item, 5-point anchored severity scale. Mean score is obtained by adding all scores and dividing by 10. A mean score of 0.3 is the upper limit for no EPS	5–10 minutes to complete. Item domains include gait, arm dropping, shoulder shaking, elbow rigidity, wrist rigidity, leg pendulousness, head dropping, eye blinking, tremor, and salivation
Barnes Akathisia Scale (BAS)	Drug-induced akathisia	4 items including three 4-point anchored severity scored items and a 5-point global rating score item. Total score of 12 possible	10 minutes to complete. Items 1-3 (objective observation of restlessness, subjective awareness of restlessness, and subjective distress related to restlessness). Diagnostic criteria: requires both objective and subjective ratings of at least one in either two subjective items

EPS, extrapyramidal symptoms.
Data from Schooler and Chengappa[21] and Guy.[19]

Validity, in contrast, is the ability of a scale to measure what it was designed to measure. Various validity tests are performed on a rating scale to ensure that the scale assesses the appropriate aspects of the illness (content validity), the correlation with diagnoses or clinical change (concurrent validity), and the extent to which the scale measures symptom traits in contrast to a specific symptom (construct validity).

Psychiatric rating scales should not be confused with psychologic tests such as neuropsychologic and intellectual assessments and are best used as only one part of a comprehensive diagnostic plan. Tables 71–3, 71–4, and 71–5 describe commonly used patient-rated and clinician-rated scales for a variety of disease states.[18–20,23–26]

SYSTEMATIC MEASUREMENT OF COGNITIVE FUNCTION

Neuropsychiatric rating scales provide specific information such as the rate of change and severity of cognitive decline or improvement. They are useful in situations in which repeated measurements of a patient's mental status are needed because they allow the clinician to determine response to an intervention (e.g., medication) in a more systematic manner. In addition, some cognitive function measures are useful screens for Alzheimer disease and other causes of cognitive decline. A number of cognitive rating scales are available, the most common being the Mini-Mental Status Examination (MMSE).

The MMSE is a structured interview that globally assesses many cognitive domains, including orientation, visuospatial organization, memory, and reasoning to determine an overall score of cognitive function. The maximum score is 30, and a score of 23 or less is indicative of significant cognitive impairment. The MMSE takes 5 to 10 minutes to administer and is used routinely in the clinical setting.[27] Other examples of cognitive rating scales include the Blessed Information Memory Concentration test (BIMC), the Dementia Rating Scale (DRS-2), the Clock Drawing test (CDT), and Alzheimer's Disease Assessment Scale.[28–31]

Most of the rating scales involve a structured interview that requires clinician training to ensure accurate administration. Noise and distraction can affect the patient's performance ability; therefore, the interview should be conducted in a quiet area with adequate lighting. The interviewer should speak slowly and clearly to the patient when providing instructions or asking questions.

PSYCHOLOGICAL TESTING

Although most clinicians do not administer psychological testing, they can use the results to evaluate the role of medication in relationship to the diagnosis. Psychological testing alone cannot establish a firm diagnosis but can be a useful diagnostic tool when coupled with clinical judgment. Types of psychological testing include personality tests (e.g., Minnesota Multiphasic Personality Inventory-2), intelligence tests (e.g., Wechsler Adult Intelligence Scale–Revised, Wechsler Intelligence Scale for Children–Revised), projective tests (e.g. Rorschach), and neuropsychologic tests (e.g., Bender Visual Motor Gestalt Test).[3]

TABLE 71-3 Schizophrenia Rating Scales

Rating Scale	Type	Scoring	Comments
Brief Psychiatric Rating Scale (BPRS)	Clinician rated	18 items, 7-point severity scale: mildly ill ≃32, moderately ill ≃44, markedly ill ≃55, and severely ill ≃70 when correlated to the CGI	The anchored BPRS provides descriptions of each severity rating to increase the interrater reliability. The BPRS has four clusters of symptoms: thinking disturbance, anxious depression, withdrawal-retardation, and hostility-suspiciousness
Positive and Negative Syndrome Scale (PANSS)	Clinician rated	30-item scale, 7-point severity scale: mildly ill ≃57, moderately ill ≃75, markedly ill ≃95, and severely ill ≃116 when correlated to the CGI	Based on the 18-item BPRS for assessing the presence or absence of positive and negative symptoms, and psychopathology of schizophrenia
Clinical Global Impression (CGI) Scale CGI (S): Severity of Illness CGI (I): Global Improvement CGI: Efficacy Index	Clinician rated	Severity of illness and global improvement on 7-point rating scales. Efficacy index: 1–4 marked improvement; 5–8 moderate; 9–12 minimal; 13–16 unchanged/worse	Observational and non-symptom specific for assessing three global subsets: severity of illness, global improvement, and efficacy index measures both therapeutic and side effects

BPRS and PANSS data from Leucht et al.[18,20]

TABLE 71-4 Depression and Bipolar Disorder Rating Scales

Rating Scale	Type	Scoring	Comments
Hamilton Depression Scale (HAMD or HDRS)	Clinician rated	17-item scale; <6 = normal mood; 17–25 = moderate depression; >25 = severe depression	Used to screen patients for drug studies and to determine severity of symptoms and treatment outcome. HDRS is the standard to compare other depression rating scales against
Montgomery-Asberg Depression Rating Scale (MADRS)	Clinician rated	10-item, 7-point scale. For each item: 0 = no symptoms; 6 = severe symptoms	Differentiates between all the intermediate grades of depression. Decreases bias in patients with other medical illnesses and increased somatization (varied unexplained physical symptoms)
Beck Depression Inventory (BDI)	Patient rated	21-item scale; 0–9 = normal; 10–15 = mild depression; 16–19 = mild-moderate; 20–29 = moderate-severe; 30–63 = severe depression	The standard for depression self-rating scales and an objective measure of change in symptoms as a result of treatment
Zung Self-Rating Depression Scale (ZSDS)	Patient rated	20-item scale, 4-point severity; <50 = normal; 50–59 = minimal-mild; 60–69 = moderate-marked; ≥70 severe depression	Severity rated by frequency of occurrence of symptoms. May not be as sensitive in measuring changes in severity of symptoms
Patient Health Questionnaire (PHQ-9)	Patient rated	9-item, 4-point scale. For each DSM-IV depression criteria item: 0 = not at all; 3 = nearly every day. Score <10 = minimal depression symptoms	Commonly used in primary care to establish a diagnosis of depression and assess severity of depressive symptoms
Quick Inventory of Depressive Symptomatology (QIDS-C [Clinician] and QIDS-SR [Patient])	Clinician and patient rated	16-item scale; scores range from 0–27; 0–5 = none; 6–10 = mild; 11–15 = moderate; 16–20 = severe; 21–27 = very severe	Used to assess symptom severity and symptomatic change. QIDS-SR found to be as sensitive to symptom change as the HDRS. Has usefulness in both clinical and research settings
Young Mania Rating Scale (YMRS)	Clinician rated	11-item scale; 5-point severity; 13 = minimal; 20 = mild; 26 = moderate; 38 = severe	Used to screen patients for drug studies and to determine severity of symptoms and treatment outcome. YMRS is the standard to compare other mania rating scales against
Mood Disorder Questionnaire (MDQ)	Patient rated	15-item scale; score of ≥7 suggestive of bipolar spectrum disorder	Screens for a lifetime history of mania or hypomania. Does not assess severity of illness

TABLE 71-5 Anxiety Rating Scales

Rating Scale	Type	Scoring	Comments
Hamilton Anxiety Scale (HAM-A or HAM-AS or HAMRS)	Clinician rated	14 items, 5-point scales; scores of ≥18–20 for moderate anxiety	Consists of subscales to measure somatic and psychic anxiety
Self-Rating Anxiety Scale (Zung SAS)	Patient rated	20-item scale; 4-point intensity ratings	Correlates to the clinician-rated Anxiety Status Inventory (ASI); however, there is little information on the validity of either test
Sheehan Panic and Anticipatory Anxiety Scale (SPAAS)	Patient and clinician rated	3-part scale	Measures panic attacks, anticipatory anxiety, and limited symptom attacks
Yale-Brown Obsessive-Compulsive Scale (YBOCS)	Clinician rated	Semi-structured interview	Consists of several clusters of obsessions and compulsions. Used to assess baseline severity and change in treatment studies

CONCLUSIONS

Patient assessment is the basis from which a pharmaceutical care plan evolves. Problem identification and therapeutic monitoring cannot occur until a thorough assessment is completed. The initial assessment provides the basis for evaluating response to therapy throughout the course of treatment. Psychiatric assessment requires empathy and good listening skills on the part of the clinician because it is based primarily upon subjective interpretation and not objective tests. With careful data collection, clinicians can make substantial contributions to care that improve patient outcomes.

ACKNOWLEDGEMENTS

The authors are grateful to Patricia A. Marken, PharmD, FCCP, BCPP, Professor of Pharmacy Practice at the University of Missouri–Kansas City, College of Pharmacy, for her significant contributions to this chapter in previous editions.

CHAPTER 72

Childhood Disorders

JULIE A. DOPHEIDE AND STEPHEN R. PLISZKA

KEY CONCEPTS

1. Inattention and impulsivity caused by attention deficit/hyperactivity disorder (ADHD) begins before age 7 years and can continue into adolescence and adulthood, often requiring ongoing drug treatment.
2. Stimulants are first-line treatment for ADHD because they are the most effective medications and have overall good tolerability. Atomoxetine, guanfacine extended release (XR), and bupropion are second-line alternatives for those unresponsive to or unable to tolerate stimulants. Clonidine and guanfacine can also be considered as adjuncts to stimulants to optimize treatment of oppositional symptoms or persistent insomnia.
3. Coexisting disorders or symptoms such as anxiety, mood, and behavior dysregulation have an impact on drug selection for ADHD and can necessitate the use of additional agents.
4. Tourette's disorder presents with both motor and vocal tics, which are present during childhood, plateau during adolescence, and can continue during adulthood with a fluctuating course.
5. The decision to medicate patients with Tourette's disorder is based on the degree of concern perceived by the patient, symptom severity, and comorbid disorders.
6. Individuals with Tourette's disorder are particularly sensitive to medication side effects, so medication dosing must be individualized carefully, and close monitoring is essential.
7. Nondrug approaches to enuresis management, such as behavioral interventions and the use of bed-wetting alarms, are preferred because of lasting cure rates and avoidance of drug side effects.
8. Desmopressin tablets are preferred over tricyclic antidepressants (TCAs) because of better safety and tolerability. Both desmopressin and TCAs have a rapid onset of effect (1–2 weeks); however, the relapse rate on drug discontinuation is high.

All neuropsychiatric disorders can first present during childhood.[1] Attention deficit/hyperactivity disorder (ADHD), Tourette's disorder, and enuresis are the focus of this chapter because, by definition, the onset of symptoms explicitly occurs during childhood.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Treating children with psychotropic drugs requires a very different approach than treating adults. Children undergo neurologic, physiologic, and psychosocial changes throughout development. Age-related pharmacodynamic and pharmacokinetic differences can alter drug disposition and response. Well-defined diagnostic criteria guide drug selection;[1] however, comorbid disorders present treatment challenges.[2,3] Children may not be able to articulate symptom response or adverse effects of a medication. Psychotropic drug treatment of children is intended to control symptoms or behaviors that impair learning and development.[2,3]

The psychiatric assessment of a child requires obtaining information from the child, parents, caregivers, and teachers.

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

A diagnosis of ADHD should be considered whenever a child presents with developmentally inappropriate inattention, impulsivity, and/or hyperactivity. Symptom presence and severity vary with the situation. It is unusual for a child to display signs of the disorder in all settings or even in the same setting at all times.[1]

CLINICAL PRESENTATION AND EPIDEMIOLOGY

1 The onset of ADHD is typically by the age of 3 years and must occur by age 7 to meet the diagnostic criteria of the *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision; *DSM-IV-TR*). However, recent studies in adults are challenging the age of onset criteria, suggesting little difference in functional impairment and response to methylphenidate in adults who meet onset criteria before age 7 and those who meet all criteria except age of onset.[5] ADHD occurs in 6% to 9% of children and is estimated to be present in 4% of adults.[3,4] In the United States, four boys are diagnosed with ADHD for every girl. This difference is likely because of higher rates of oppositional defiant disorder and conduct disorder in boys, compared with girls; thus, referrals for assessment are higher for boys. Symptoms can persist lifelong for both sexes, but hyperactivity is much less prominent in adolescence and adulthood.[3,6–8]

CLINICAL PRESENTATION OF ADHD

General

- Onset of symptoms must be before 7 years of age.

Symptoms

- Six or more of the symptoms must be present for 6 months; significant impairment must be seen in two or more settings

(e.g., home and school); symptoms must be documented by parent, teacher, and clinician.

- *Inattention*
  - Often fails to give close attention to details or makes careless mistakes in schoolwork or other activities
  - Often has difficulty sustaining attention
  - Often has difficulty organizing tasks and activities
  - Avoids tasks that require sustained mental effort
  - Often does not seem to listen when spoken to directly
  - Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace
  - Is easily distracted by extraneous stimuli
  - Is often forgetful in daily activities
  - Loses things necessary for activities
- *Hyperactivity and impulsivity*
  - Often fidgets with hands or feet or squirms in seat
  - Often leaves seat when remaining seated is expected
  - Often runs about or climbs excessively at inappropriate times
  - Often has difficulty playing quietly
  - Often interrupts or intrudes on others

Data from American Psychiatric Association. Disorders usually First Evident in Infancy, Childhood or Adolescence. Diagnostic and Statistical Manual of Mental Disorders. 4th ed. Text rev. Washington, DC: American Psychiatric Association 2000:39–134.

Inattention and distractibility can be symptoms of an anxiety, mood, or psychotic disorder.[3,4,6] In some cases, other disorders coexist with ADHD; learning deficiencies and conduct or oppositional disorders are common comorbid conditions.[3,4,6] The presence of multiple comorbid conditions, particularly conduct or mood disorder, can increase the likelihood of ADHD chronicity into adulthood.[2,3,6,7]

Prescriptions for ADHD medication are increasing in all age groups, particularly in adolescents and young adults.[3,9] A National Poison Control Center study estimates that between 1998 and 2005, prescriptions for teenagers and preteenagers increased 133% for amphetamine products and 52% for methylphenidate products, 80% for both.[9]

ETIOLOGY AND PATHOPHYSIOLOGY

Both genetic and nongenetic factors are implicated in the pathogenesis. First-degree relatives of an individual with ADHD have a four- to eightfold increased chance of developing ADHD compared with the general population; monozygotic twins have up to a 90% concordance rate for ADHD.[3,10] Children with fetal alcohol syndrome, lead poisoning, and meningitis have a higher incidence of ADHD symptomatology.[3,4] ADHD is associated with a variety of environmental risks, including obstetric adversity, maternal smoking, and adverse parent–child relationships.[3,4] Dietary causes are unlikely.[3,4]

Although there are no definitive pathophysiologic markers for ADHD, imaging studies show subjects with ADHD have decreased total brain volume relative to controls in multiple brain regions (right prefrontal cortex, caudate nucleus, anterior cingulate gyrus, and cerebellum). Global thinning of the cortex has been observed in children with ADHD, and comparative studies show there is a delay in cortical thickening in ADHD brains relative to age-matched controls.[3] These brain changes are thought to impair executive functioning necessary for prioritization of tasks, decision making, motor control, and an awareness of space and time.[3,11] Alterations in the "default mode" attention network have been found in adults with ADHD.[3] A lack of connectivity between the prefrontal cortex and precuneus (located in the midline of the parietal lobe) is associated with failure of suppression of the default mode network, causing lapses in attention and inhibitory control.[3]

Genetically mediated changes in serotonergic, cholinergic, and most notably dopaminergic function have been documented in children and adults with ADHD.[3,10,11] Deficits in the dopaminergic reward pathway in the ADHD brain impair the ability to delay gratification, resist distractions, regulate arousal, and attend to information or tasks that are dull or repetitive.[12] This dysfunction involves multiple dopaminergic receptors (D_2, D_3, D_4, and D_5) and dopamine active transporter protein (DAT), which is presynaptic.[11,12] Norepinephrine and epinephrine are agonists at dopaminergic receptors and are modulated by DAT as well.[13,14] Treatment with stimulants has been shown to improve the rate of cortical thickening, and pharmacotherapy can improve or normalize dopaminergic receptor function.[3,11] Those with demonstrated abnormalities in DAT seem to respond better to methylphenidate and atomoxetine.[13,14]

Effective treatments modulate dopamine and norepinephrine to improve executive functioning, regulate arousal, and sustain attention for improved performance. The clinical response associated with stimulants is not paradoxical and is not diagnostic for ADHD because stimulants can increase attention, decrease motor activity, and improve learning tasks in those with subclinical ADHD or in individuals with such problems from other sources (e.g., fatigue).[3,4,13]

TREATMENT

STIMULANTS

2 3 Stimulants are considered first-line therapy in most cases of ADHD; however, comorbid conditions impact the drug selection process. Pharmacotherapy should be considered whenever a thorough diagnostic assessment results in a diagnosis of ADHD. Several studies demonstrate the superiority of stimulants over behavioral interventions in alleviating core symptoms of ADHD.[3,4,6] Emerging literature shows improvement in academic performance in medicated children with ADHD versus those unmedicated.[15,16,17] One National Institutes of Health (NIH) study of 594 fifth graders with ADHD showed those medicated (greater than 90% took stimulants) had 2.9 points higher math scores and 5.4 points higher reading scores compared with unmedicated children.[16] Another study involving 363 10- to 18-year-olds with ADHD showed medication improved but did not normalize cognition.[18]

Multimodal treatment, individualized to the specific needs of the child and family, is crucial for an overall positive therapeutic outcome.[4,16,19] Table 72–1 describes behavioral interventions for ADHD. Multimodal treatment includes parent training, family therapy, classroom interventions, and contingency management (e.g., rewards for good behavior).[4,6,7] Figure 72–1 provides an algorithm for drug selection in the treatment of ADHD.

Stimulants (e.g., methylphenidate, dexmethylphenidate, mixed amphetamine salts, and dextroamphetamine) are the most effective drug treatment options, with efficacy ranging from 70% to 96%.[3,4,6]

Methylphenidate and amphetamines block dopamine and norepinephrine reuptake; amphetamines also increase catecholamine release.[13] Both drugs inhibit monoamine oxidase (MAO), or

TABLE 72-1 Behavioral Interventions for ADHD

Technique	Description	Example
Positive reinforcement	Providing rewards or privileges contingent on the child's performance	Child completes an assignment and is permitted to play on the computer
Time-out	Removing access to positive reinforcement contingent on performance of unwanted or problem behavior	Child hits sibling impulsively and is required to sit for 5 minutes in the corner of the room
Response cost	Withdrawing rewards or privileges contingent on the performance of unwanted or problem behavior	Child loses free-time privileges for not completing homework
Token economy	Combining positive reinforcement and response cost. Child earns rewards and privileges contingent on performing desired behaviors and loses the rewards and privileges based on undesirable behavior	Child earns stars for completing assignments and loses stars for getting out of seat. The child cashes in the sum of stars at the end of the week for a prize

amphetamines, more potently than methylphenidate.[13] Because different stimulants work through slightly different mechanisms, the lack of response to one chemical class of stimulant (e.g., methylphenidate or dexmethylphenidate) does not preclude response to another class (e.g., dextroamphetamine or mixed amphetamine salts).[3,4,6]

Stimulant dosing should be titrated for maximum individual efficacy and minimum side effects (see Table 72–2).[3,4]

With immediate-release stimulants, most patients require a two or three times daily dosing schedule because of the short half-lives of these drugs (2–4 hours for methylphenidate and dexmethylphenidate and ~4–6 hours for dextroamphetamine or mixed

TABLE 72-2 Stimulant Drugs Used in the Treatment of ADHD

Stimulant	Duration of Effect	Initial Dose and Available Strengths	Usual Dosing Range Maximum Dose
FDA approved for children ≥6years old			
Methylphenidate C-II[a]			
Short-acting IR Ritalin, methylin, generics	3–5 hours	5 mg two or three times daily; increase by 5–10 or 20 mg/day at weekly intervals	5–20 mg two or three times a day; max dose: 60 mg/day
Intermediate-acting Ritalin SR Methylphenidate SR Metadate ER Methylin ER	3–8 hours	SR, ER doses; corresponds to the IR dose	20–40 mg every A.M. or 40 mg every A.M. and 20 mg in the early afternoon; max dose: 60 mg/day
Long-acting Metadate CD 30% IR, 70% ER beads	8–12 hours	20 mg every A.M.; available as 10, 20, and 30 mg	20–40 mg every A.M. and 20 mg in the early afternoon; max dose: 60 mg/day
Ritalin LA 50% IR, 50% ER beads		20 mg every A.M.; available as 20, 30, and 40 mg	20–60 mg/day, given every A.M.; max dose: 60 mg/day
Concerta (OROS controlled-release delivery)			
ER inner compartments coated with IR methylphenidate		18 mg every A.M.; available as 18, 27, 36, and 54 mg; 90% bioavailability of IR	27–72 mg/day, given every A.M.; max dose: 72 mg/day
Daytrana methylphenidate transdermal system	12 hours when worn for 9 hours	10 mg (12.5 cm^2) applied to clean, dry area on hip each morning and removed after 9 hours	10 to 30 mg (12.5–37.5 cm^2) Drug active for 3 hours after patch removal
Dexmethylphenidate (Focalin) C-II FDA approved for children ≥6 years old	3–5 hours	2.5 mg every A.M. or twice daily; available as 2.5, 5, and 10 mg tablets	5–10 mg/day given twice a day; max initial dose: 7.5 mg/day; max dose: 20 mg/day
Focalin XR 50% IR, 50% ER beads	8–12 hours	5 mg every A.M.; available as 5, 10, and 20 mg capsules	5–20 mg/day, given every A.M. max dose: 20 mg/day
Mixed amphetamine salts C-II FDA approved for children ≥3 years old *Short- to intermediate-acting* Mixed amphetamine generics, Adderall	4–6 hours	2.5 mg every A.M. once or twice daily dosing	10–40 mg/day (divided in two doses)
Dextroamphetamine C-II FDA approved for children ≥6 years old	4–6 hours	2.5 mg every A.M. to two or three times daily dosing	5–15 mg twice daily
Short-acting Dextroamphetamine generics Dexedrine, Dextrostat	3–5 hours	5 mg every A.M.; available as 5 and 10 mg	10–40 mg/day given twice daily
Intermediate-acting Dexedrine Spansule	5–8 hours	Available as 5, 10, and 15 mg	5–30 mg every day or 5–15 mg twice daily; max: 40 mg/day
Adderall XR 50% IR, 50% ER beads	8–12 hours	Available as 5, 10, 20, and 30 mg capsules	5–30 mg once daily in the morning; max: 30 mg/day
Long-acting	8–12 hours	Available as 20, 30, 40, 50, 60, and 70 mg capsules	Start at low end, titrate weekly to response; give in A.M.
Lisdexamfetamine (prodrug converted to dextroamphetamine) FDA approved for children >6 years old Adderall XR 50% IR beads, 50% ER beads			Longer onset compared with other dextroamphetamine products

[a]The Drug Enforcement Administration label C-II, schedule II refers to significant abuse potential.

ER = extended release, IR = immediate release, OROS, oral osmotic, SR = sustained release, XR = extended release.

Pharmacotherapy 2009;29(6):656–679; and Pliszka SR, Bernet W, Bukstein O, et al, for the American Academy of Child and Adolescent Psychiatry Work Group on Quality Issues. Practice parameter for the assessment and treatment of children and adolescents with attention deficit/hyperactivity disorder. J Am Acad Child Adolesc Psychiatry 2007;46:894–921.

amphetamine salts).[3,4] Drug response is maximal during the absorption phase, is evident in 15 to 30 minutes, and lasts 2 to 6 hours.[3,4,19]

Drug delivery systems of once-daily products (amphetamine aspartate, amphetamine sulfate, dextroamphetamine sulfate, and dextroamphetamine saccharate [Adderall XR]; methylphenidate [Concerta]; methylphenidate [Daytrana]; dexmethylphenidate [Focalin XR]; methylphenidate [Metadate CD]; and methylphenidate long-acting [Ritalin LA]) provide 8 to 12 hours of symptom control.[3,4,6] Concerta uses an oral osmotic controlled-release delivery system, whereas other oral preparations use combinations of immediate-release and extended-release beads.[3,4] Concerta is a nondeformable tablet, and it should not be given to children with gastrointestinal (GI) narrowing because of the risk of obstruction. Methylphenidate transdermal system provides 12 hours of symptom control when worn for 9 hours.[4] Older wax-matrix sustained-release (SR) products (e.g., Ritalin SR) are less effective and infrequently used.[3,4] Once-daily stimulant formulations are the preferred treatment for ADHD in most individuals due to convenience and better medication adherence.[3,4] Immediate-release formulations have the advantage of lower cost, less insomnia, and potentially fewer growth effects versus extended-release products.[3,20] Adolescents and adults with ADHD are also responsive to stimulants.[21,22] Methylphenidate is effective in adolescents and adults in doses up to 1.5 mg/kg daily.[3,4,20] Lisdexamfetamine is a prodrug conjugated to an amino acid that requires cleavage during metabolism to the active dextroamphetamine. It has a longer onset of effect but may provide a smoother blood level compared with extended-release formulations. It is intended to pose less abuse potential.[3,4]

ADVERSE EFFECTS

The most common adverse effects of stimulants and their management strategies are listed in Table 72–3. Uncommon to rare but potentially serious adverse effects are discussed in the following sections.

TABLE 72-3 Stimulant Adverse Effects and Their Management

Adverse Effect	Recommendation/Management Strategy
Common	
Reduced appetite, weight loss	Give high-calorie meal when stimulant effects are low (at breakfast or at bedtime), or consider cyproheptadine at bedtime
Stomachache	Administer stimulant on a full stomach, lower dose if possible
Insomnia	Give dose earlier in the day; lower the last dose of the day or give it earlier; consider a sedating medication at bedtime (guanfacine, clonidine, melatonin, or cyproheptadine)
Headache	Divide dose, give with food, or give an analgesic (e.g., acetaminophen or ibuprofen)
Rebound symptoms	Consider longer-acting stimulant trial, atomoxetine, or antidepressant
Irritability/jitteriness	Assess for comorbid condition (e.g., bipolar disorder); reduce dosage; consider mood stabilizer or atypical antipsychotic
Uncommon to rare	
Dysphoria	Reduce dosage; reassess diagnosis; consider alternative therapy
Zombie-like state	Reduce dosage or change stimulant medication
Tics or abnormal movements	Reduce dosage; consider alternative medication
Hypertension, pulse fluctuations	Reduce dosage; change medication
Hallucinations	Discontinue stimulant; reassess diagnosis; mood stabilizer and/or antipsychotic may be needed

Pharmacotherapy 2009;29(6):656–679; and Pliszka SR, Bernet W, Bukstein O, et al, for the American Academy of Child and Adolescent Psychiatry Work Group on Quality Issues. Practice parameter for the assessment and treatment of children and adolescents with attention deficit/hyperactivity disorder. J Am Acad Child Adolesc Psychiatry 2007;46:894–921.

Psychiatric

The Food and Drug Administration (FDA) has added warnings to the labeling of all stimulants and atomoxetine. Hundreds of postmarketing reports of three broad categories of psychiatric adverse events have been associated with stimulants: psychosis or mania, aggression or violent behavior, and severe anxiety or panic attacks. All of these reactions require dose reduction or cessation of stimulant therapy and supportive treatment.[3,4]

Cardiac

A boxed warning for cardiovascular risks including sudden unexplained death has been added to ADHD stimulant drug labeling.[3] Clinical trial data show that children who take stimulants for ADHD can have an increased heart rate by ~5 beats/minute and/or increased blood pressure by 2 to 7 mm Hg.[23] A 10-year review showed a 20% increased risk for emergency department visits for cardiac symptoms in those taking either methylphenidate or amphetamine.[23] Of note, these individuals were more likely to have a coexisting anxiety disorder.

Stimulant products generally should not be used in pediatrics or adults with known structural cardiac abnormalities. The American Heart Association recommends careful screening of all children and adolescents prior to initiating pharmacologic therapy for ADHD, including a detailed patient and family history and physical examination. Ideally, a baseline electrocardiogram (ECG) should also be obtained, along with routine monitoring of pulse and blood pressure.[24] The FDA did not find the risk of sudden unexplained death to be greater in those taking stimulants than in the general population; therefore, no restriction in stimulant use has been recommended.[25]

Growth

Two reviews that analyzed approximately 32 studies indicated that stimulant treatment of ADHD can affect growth, but the effects are minimal or insignificant for most children. A study of 579 children showed a decrease of ~1 cm/year (~0.5 inch) in height over 1 to 3 years of continuous treatment with methylphenidate and a weight deficit of 3 kg (6.6 lbs) in the first year of treatment and 1.2 kg (2.6 lbs) in the second year of treatment.[3] Amphetamine products may be associated with more prominent growth effects than methylphenidate according to separate studies.[3] Proposed mechanisms of stimulant effects on growth include alterations in growth hormone or growth factor, decreased thyroxine secretion, and suppression of appetite leading to reduced caloric intake.[3,4,20]

In most cases, children should be given a drug-free trial every year.[4] Time off stimulant appears to lessen stimulant growth suppressant effects, but evidence is lacking to firmly determine the impact of drug holidays on growth.[3,4] Consideration must be given to the risks of negative effects on learning, socialization, and self-image while off stimulant therapy when determining the frequency and duration of the drug-free trial. Drug holidays are important because they provide time to reassess the need for continued treatment.[3,4] Drug dosage often varies from year to year, largely because of age-related pharmacokinetic changes. As a child develops, hepatic metabolism slows, and volume of distribution increases.

NONSTIMULANTS

2 Extended-release atomoxetine and guanfacine are second-line alternatives to the stimulants for treatment of ADHD in children and adolescents. Atomoxetine is also approved in adults. Their potential benefits relative to stimulants include no abuse potential, less potential for growth effects, and less sleep disturbance.[3,4] See Table 72–4 for dosing.

Atomoxetine is a selective norepinephrine reuptake inhibitor that should be taken in divided doses in the morning or late afternoon by children for improved tolerability. Adults can take it once daily, usually in the morning.[3,4] Placebo-controlled, short-term trials (6–12 weeks) have shown that atomoxetine is effective in reducing ADHD symptoms in children, teens, and adults, and 9-month continuation studies show ongoing benefit for responders. A controlled trial comparing atomoxetine, oral osmotic methylphenidate, and placebo over 6 weeks in 6- to 16-year-old patients showed that both drugs were significantly better than placebo at improving ADHD symptoms, but oral osmotic methylphenidate was superior to atomoxetine.[3,4]

Atomoxetine has a significantly slower onset of therapeutic effect than stimulants (2–4 weeks vs 1 hour with an effective stimulant dose). Atomoxetine is sometimes combined with a stimulant in partially responsive patients based on case series describing fewer late-day rebound effects and better sleep when atomoxetine is given in the evening; however, adverse effects are additive.[3,4,6]

Guanfacine and clonidine are central α_2-adrenergic agonists, acting both presynaptically to inhibit norepinephrine release and postsynaptically to increase blood flow in the prefrontal cortex. Increased blood flow in the prefrontal cortex has been shown to enhance working memory and executive functioning. Both interact with a multitude of neurotransmitter systems, including catecholamine, indolamine, α_2-receptors on parasympathetic neurons, opioids, imidazole, and amino acid systems.[13] Guanfacine has a longer elimination half-life (12–18 hours) compared with clonidine (2.5–4 hours), and its greater selectivity for the α_{2a}-receptor, compared with clonidine, imparts less sedation. Clonidine and immediate-release guanfacine are not as effective as stimulants for monotherapy treatment. They are prescribed frequently as

TABLE 72-4 Dosing and Adverse Effect Monitoring of Nonstimulant Drugs for ADHD

Drug	Dosing Range and Titration Schedule	Adverse Effect Monitoring
Antidepressants		
Atomoxetine (Strattera)	≤70 kg (≤154 lbs): start at 0.3–0.5 mg/kg every A.M. or twice daily, max: 1.4 mg/kg/day; ≥70 kg (≥154 lbs): start at 40 mg every A.M. or twice daily, max: 100 mg/day	Nausea, anorexia, ↑ blood pressure, ↑ pulse, insomnia, fatigue, sedation, severe liver injury, suicidality
Bupropion (Wellbutrin SR, XL)	50–300 mg/day; 3 mg/kg/day by end of week 1; can increase to 6 mg/kg/day or maximum of 300 mg/day as tolerated	Nausea, insomnia, rash, tics; dose-related risk of seizures
Tricyclic antidepressants: imipramine, desipramine, or nortriptyline	50–150 mg/day; start at 0.5–1 mg/kg/day; increase as tolerated to 2–3 mg/kg/day; max: 300 mg/day of desipramine (adults only) or 150 mg/day nortriptyline	Sedation, dizziness, constipation, heart block (check ECG), weight gain, overdose toxicity, rapid heartbeat
Antipsychotics		
Aripiprazole[a] (Abilify)	2–5 mg daily; can titrate weekly as tolerated to response (usual range: 5–20 mg/day)	Nausea, restlessness, insomnia extrapyramidal symptoms, dizziness, sedation
Haloperidol[a](Haldol)	0.5–1 mg twice daily; can titrate every 3–4 days as tolerated to response (usual range: 0.5–5 mg/day)	Extrapyramidal symptoms, dizziness, ↑ prolactin, sedation
Olanzapine[a] (Zyprexa)	2.5–5 mg every day; can titrate every 3–4 days as tolerated to response (usual range: 7.5–15 mg/day)	Sedation, severe weight gain, restlessness, extrapyramidal symptom Diabetes, marked hyperlipidemia (never a first-line treatment)
Quetiapine[a] (Seroquel)	25–50 mg twice daily; can titrate every 3–4 days as tolerated to response (usual range: 200–600 mg/day)	Sedation, dizziness, weight gain, diabetes, hyperlipidemia
Risperidone[a] (Risperdal)	0.25–0.5 mg twice daily; can titrate every 3–4 days as tolerated to response (1–4 mg/day)	Extrapyramidal symptoms, dizziness, ↑ prolactin, hepatotoxicity, weight gain Diabetes, hyperlipidemia
Ziprasidone[a] (Geodon)	10–20 mg twice daily; can titrate every 3–4 days as tolerated to response (usual range: 40–120 mg/day	Nausea, restlessness, insomnia extrapyramidal symptoms, sedation, QTc prolongation
Other		
Clonidine (Catapres)	0.05 mg two or four times daily; can increase as tolerated to 0.1–0.4 mg/day	Sedation, dizziness, heart block (check ECG), constipation
Guanfacine (Tenex)or guanfacine extended release (Intuniv)	0.5 once or twice daily; can increase as tolerated to 1–4 mg/day Give 1 mg in the A.M., titrate weekly to response	Same as above with potentially lower risk of sedation Effective dose higher in heavier children

ADHD = attention deficit/hyperactivity disorder, ECG = electrocardiogram; SR = sustained release, XL = extended-length.

[a]Short-term use (1–4 months) only for severe aggression associated with ADHD.

From Dopheide JA, Pliszka SR. Attention deficit hyperactivity disorder: An update. J Clin Psych 2008;69(Suppl 4):26–36.

adjuncts to reduce disruptive behavior, control aggression, or improve sleep.[3,4,6]

Extended-release guanfacine is approved for children and adolescents based on two large placebo-controlled trials involving over 300 patients each and long-term safety studies.[26,27] It appears at least as effective as other nonstimulants and is an acceptable second-line agent for children and adolescents unresponsive to or unable to tolerate stomach upset or insomnia with stimulant medications. Extended-release guanfacine is more sedating than stimulants or atomoxetine; therefore, sleepiness during the school day requires careful monitoring.

Bupropion, a monocyclic antidepressant, is a weak dopamine and norepinephrine reuptake inhibitor with no significant direct effect on serotonin or MAO. Its active metabolites augment noradrenergic and dopaminergic function. Investigations with bupropion in children demonstrated efficacy greater than placebo in two controlled trials and efficacy comparable with methylphenidate ($n = 15$ children) in another controlled trial.[3,4] Bupropion has less appetite suppression compared with stimulants but has a greater risk of seizures. It also may be effective in adults at antidepressant doses.[3,4,6,8]

Tricyclic antidepressants (TCAs) are last-line agents because they are the most dangerous in overdose and pose the greatest risk for cardiovascular side effects.[4,6] Imipramine and desipramine are the most systematically studied TCAs in the treatment of ADHD, although nortriptyline is also effective.[4,6] The onset of TCA clinical response occurs within the first 2 to 4 weeks.[4,6]

Variability in dosage requirements for atomoxetine, bupropion, and TCAs can be due to interpatient variability in plasma concentration achieved at a given dose. All are metabolized via cytochrome P450 (CYP) 2D6, and bioavailability and half-life can be 4 to 8 times greater in those taking a CYP2D6 inhibitor (e.g., bupropion, fluoxetine, or paroxetine) or in poor metabolizers. For example, atomoxetine's half-life is 5 hours in extensive metabolizers and 19 hours in poor metabolizers.[3,6] Bupropion is metabolized faster in prepubertal children, making twice daily dosing optimal for efficacy (even for bupropion SR).[6] Twice-daily dosing of atomoxetine is optimal in children and adolescents to improve tolerability.[3,6] Once-daily dosing of bupropion or atomoxetine is possible for most adults. If tolerance develops after months of therapy, a dosage adjustment can be necessary to compensate for age-related changes in distribution and metabolism.

3 Lithium and anticonvulsants are used increasingly to control aggression and explosive behavior in patients with a diagnosis of ADHD. Some patients actually can have childhood-onset bipolar disorder or combined ADHD–bipolar disorder.[3,6] Lithium, valproate, and carbamazepine are effective for explosive behavior, aggression, and impulsivity, but they are not beneficial treatments for a child with the inattentive subtype of ADHD. Dosing starts in low divided doses with titration over 1 to 2 weeks to therapeutic response.[6,28]

Conventional antipsychotics improve symptoms of hyperactivity and impulsivity but can have negative effects on learning and cognitive functioning and can cause extrapyramidal side effects

(e.g., dystonia and tardive dyskinesia) that limit their usefulness.[3,4,6,28] The atypical antipsychotics risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole have been used to control severe aggression in refractory cases of ADHD, particularly if conduct disorder or bipolar disorder coexists.[29,30] More studies are needed to clarify their place in therapy.[6,20,28–31]

If multiple drugs are started simultaneously, it is impossible to determine the impact of each drug. The predominance and urgency of symptoms guide the drug-selection process (see Fig. 72–1). For example, if a child presents as severely anxious or depressed with associated attentional problems, then an antidepressant should be initiated first with monitoring to determine if attentional symptoms improve.[3,4,6] When a child presents with severe ADHD and associated anxiety or depression, a stimulant should be initiated to treat the more severe ADHD. If ADHD symptoms improve significantly, but anxiety or depression persists, then an antidepressant can be added.[3,4,6] Careful monitoring is needed to detect drug interactions that lead to higher drug plasma levels and increased adverse effects.[6,28,32] Studies show that stimulants do not routinely make anxiety disorders worse, but they might not improve symptoms either.[3,4] In a child with epilepsy, methylphenidate is safe and effective; however, the child should be stabilized and seizure-free on an anticonvulsant prior to initiation of the stimulant.[33]

Adverse Effects

Possible adverse effects of atomoxetine, and their management, are similar to those of stimulants, including psychiatric and cardiac adverse effects (see Table 72–4). Atomoxetine has been associated with less growth suppression compared with stimulants, 0.44 cm over 2 years of treatment. It has a greater risk of fatigue, sedation, and dizziness compared with stimulants and bupropion. Unlike stimulants, atomoxetine labeling includes a bolded warning of potential for severe liver injury following reports in two patients. Also, it is the only FDA-approved ADHD medication with a labeled warning for new onset suicidality, 0.4% in atomoxetine treated patients versus 0% in patients receiving placebo.[3,4,6]

The most common side effects of clonidine and guanfacine are dose-dependent sedation, hypotension, and constipation.[3,4] Sedation usually subsides after 2 to 3 weeks of therapy.[3,4,6] Of concern are reports of bradycardia, syncope, rebound hypertension, heart block, and sudden death with clonidine.[6,34,35] Four children have died on the combination of methylphenidate and clonidine; however, complicating factors make it impossible to link the drug combination directly with the cause of death.[35] Overdoses, concurrent clonidine and stimulant administration, and missed doses of clonidine all add to the risk of adverse cardiovascular events.[32,33] Extended-release guanfacine appears to pose a lower risk of cardiac adverse effects according to available safety data.[26,27]

Bupropion's adverse effects include nausea, which can resolve over time or with slower dosage titration, and rash, which can require discontinuation of therapy if severe (see Table 72–4). Bupropion should not be used in children with a seizure or eating disorder because of unacceptable risk of seizures in these patients. Bupropion can cause or exacerbate tics.[3,4,6]

Possible central nervous system (CNS) adverse effects of TCAs include dizziness, aggressiveness, excitement, nightmares, insomnia, forgetfulness, and irritability. Similar to other antidepressants, TCAs carry a warning of the risk of new-onset suicidality in pediatric patients.[32] TCAs should be taken throughout the week and not just on school days. TCA-withdrawal effects are severe in children and include nausea, vomiting, and diarrhea.[32] Signs of CNS toxicity are confusion, impaired concentration, hallucinations, and delusions.

PHARMACOECONOMIC CONSIDERATIONS

A conservative annual cost of illness estimate for ADHD in 2005 dollars was calculated at $14,576 per child (range $12,000–$18,000). This estimate includes lost work for parents; the cost of special education, behavioral interventions, medications, and doctor and clinic visits; and the use of the juvenile justice system.[36] A large study found behavioral interventions were more expensive than immediate-release stimulant medication initially, but the long-term effects (e.g., lower rates of delinquency and substance abuse) lower costs. Atomoxetine was found most cost effective for those who could not take stimulants due to a lack of efficacy or poor tolerability.[37]

Once-daily stimulants are approximately 3 to 5 times as expensive as immediate-release formulations, but they can save money over time with improved adherence and symptom control. A retrospective analysis comparing immediate-release methylphenidate use patterns with oral osmotic methylphenidate use patterns in 5,939 patients over 34 months found that its use was associated with longer treatment periods, increased patient adherence, and fewer emergency room visits for injury, potentially decreasing overall costs.[38]

EVALUATION OF THERAPEUTIC OUTCOMES

Careful documentation of baseline symptoms and complaints over a 1-month predrug period is essential to the evaluation of therapeutic and adverse outcomes. Investigation regarding family history of psychiatric disorders and cardiac disease is essential to determine risk for related adverse drug reactions and to implement appropriate monitoring.[3,4] Baseline symptoms can be measured using videotapes, clinician rating scales (e.g., ADHD rating scale IV, Vanderbilt ADHD diagnostic scale), or both.[3,4] In addition, height, weight, and eating and sleeping patterns should be recorded at baseline and every 3 months.[3,4]

After the initiation and titration of any drug treatment, it is necessary that parents, teachers, and clinicians assess the overall functioning of the child using standardized rating scales to determine if significant therapeutic benefit justifies continuing medication.[3,4] Therapeutic effects of the stimulants include decreased motor activity and impulsivity and increased attention span.[3,4,13,15] This suggests that stimulants are indicated for ADHD symptoms and not for primary learning disorders. The benefits of drug therapy must outweigh the potential for adverse effects.[3,4,6,7]

Substance Abuse

ADHD itself is a known risk factor for the development of a substance use disorder.[3,7] A 3-year outcome study confirmed results of earlier studies by showing that children with ADHD as a whole were at least twice as likely to engage in substance abuse compared with non-ADHD controls.[3,7] Drug therapy was not associated with substance abuse in this study; however, drug therapy was associated with higher rates of delinquency at 36 months. Conduct disorder increased the risk of delinquency and substance abuse.[3,7]

Studies show nontreated or inadequately treated adolescents and adults with ADHD are at increased risk of substance abuse compared with those who are effectively treated with drug therapy.[3,39] Another study showed that children with later onset of methylphenidate initiation (ages 8–12 years) had greater substance use compared with those starting treatment earlier. It is possible that early treatment of ADHD has a protective effect toward the emergence of conduct disorder, which usually precedes antisocial personality disorder and increases the risk for delinquency and drug abuse.[3]

Atomoxetine and bupropion also require monitoring to detect changes in appetite, weight, and sleep patterns, as well as pulse or

blood pressure. An adequate trial of atomoxetine or bupropion consists of 6 weeks at maximum tolerated doses unless response occurs at a lower dose.[3,4,6]

CLINICAL CONTROVERSY

The use of stimulants to treat ADHD in individualswith substance abuse disorders is controversial. A diagnosis of ADHD confers at least a twofold greater risk of adolescent and adult substance abuse.[2,3,4] The risk is greater if conduct disorder, antisocial personality, or bipolar disorder coexists.[3,4,7] Stimulant therapy does not increase the risk of substance abuse, and effective treatment of ADHD can facilitate functioning and reduce abuse. Regardless of the benefits, however, there is significant misuse or diversion of stimulant medications among older adolescents and young adults, necessitating vigilance among prescribers and careful risk-versus-benefit assessment.[7,9,39]

When guanfacine or clonidine is given, careful clinical monitoring for fatigue, dizziness, and autonomic changes (e.g., blood pressure and pulse) is recommended.[3,4] The American Heart Association has stated that electrocardiographic monitoring is not required for clonidine treatment in children, although many clinicians continue to assess for ECG changes.[33] When discontinuing treatment, clonidine and guanfacine should be withdrawn slowly (0.05 mg clonidine/0.5 mg guanfacine reductions every 3 days) to prevent rebound hypertension or behavioral dyscontrol.[3,4] A therapeutic trial requires 1 to 2 months to assess therapeutic response, although increased sleep usually occurs immediately.

The effects of TCAs on the ECG should be monitored carefully. Of more concern are reports of sudden death in children taking desipramine or imipramine.[6,32] Children and adolescents given TCAs should have pretreatment and follow-up ECGs to assess the effects of TCA therapy on cardiac rate and rhythm.[6,32]

CONCLUSION

In summary, the preferred first-line drug therapy for ADHD is either methylphenidate, dexmethylphenidate, mixed amphetamine salts, or dextroamphetamine. Extended-release atomoxetine and guanfacine are good options for those unresponsive to or unable to tolerate stimulants. Bupropion is a safer option than a TCA, but both are declining in use, given that FDA-approved treatments are better studied. All agents require careful cardiovascular monitoring. Mood stabilizers (e.g., lithium, divalproex, and carbamazepine) and atypical antipsychotics are adjuncts for control of aggression or comorbid bipolar disorder. Other agents require further investigation before their status in the treatment of ADHD can be fully determined.

TOURETTE'S DISORDER

EPIDEMIOLOGY AND CLINICAL PRESENTATION

Tourette's disorder, also known as Tourette Syndrome, is present in 0.7% to 1% of boys and 0.4% of girls.[40,41] The essential features of this CNS disorder are multiple motor and vocal tics that must be present for more than 1 year before the diagnosis of Tourette's disorder is made. A tic is a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization.[40,41] The clinical presentation can vary from barely noticeable to debilitating, and the type of tic expressed can change over time.[1,40,41]

CLINICAL PRESENTATION OF TOURETTE'S DISORDER

General

- Onset occurs before 18 years of age.

Symptoms

- Multiple motor or one or more vocal tics are present.
- Motor and vocal tics do not need to occur concurrently.
- Tics occur many times a day (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year; during this time, there is never a tic-free period of more than 3 consecutive months.
- ***Motor Tics***
  - Eye blinking, lip licking
  - Facial twitching
  - Shoulder shrugging
  - Squatting, twirling
- ***Vocal Tics***
  - Clicks, grunts
  - Barking, yelping
  - Throat clearing, echolalia
  - Coprolalia, palilalia

Data from American Psychiatric Association.[1]

4 Transient tic disorder is diagnosed if motor or vocal tics occur for less than 1 year, with chronic tic disorder diagnosed if motor or vocal tics are present for longer than 1 year.[40,41] Tics start by age 8 and are most prominent during childhood; 50% of children experience complete attenuation of symptoms by age 18. This natural history is thought to parallel the process of nigrostriatal innervation in the developing brain, implicating Tourette's disorder as a neurodevelopmental disorder.[1,40,41]

More than 90% of children with Tourette's disorder have coexisting conditions such as ADHD (75%), mood disorders (60%), obsessive-compulsive disorder (40%), other anxiety disorders, or a combination of comorbidities. Tourette's disorder itself does not cause diminished intellectual functioning; however, the severity of tics and associated illnesses can result in significant impairment in school functioning, sometimes necessitating special education classes.[40,41] A follow-up study in adults showed that the severity of vocal tics had a more negative impact on functioning than the severity of motor tics.[42]

ETIOLOGY AND PATHOPHYSIOLOGY

Tourette's disorder is inherited in a complex polygenic pattern. Symptoms and severity of the disorder vary from one generation to another.[40,41] The neurochemical pathophysiology involves an imbalance in the interaction of dopaminergic, serotonergic, γ-aminobutyric acid (GABA)-ergic, glutamatergic, cholinergic, noradrenergic, and opioid systems in multiple brain regions, most notably the basal ganglia and caudate nucleus. The imbalance can cause a lack of regulation of the brain's inhibitory mechanisms, resulting in tics and associated behavior disorders. This multisystem etiology best explains the success of a variety of treatments.[40,41]

TREATMENT

5 Whenever symptoms are severe enough to impair the child's ability to function, drug therapy should be initiated. Psychotherapy and behavioral treatment are useful adjuncts.[40]

The α-adrenergic antagonists clonidine and guanfacine are good first-line treatment for mild motor and vocal tics associated with Tourette's disorder.[40] Their milder side effect profile compared with dopaminergic blocking drugs and efficacy for anxiety and insomnia can be an advantage. In some patients, however, the response is limited to improvement in attention and behavior with no changes in the frequency of tics. Clonidine can be initiated at 0.05 mg at bedtime with weekly titration to response. The goal dose of clonidine is 0.1 mg three times daily to a maximum of 0.2 mg three times daily.[40] Guanfacine can be initiated at 0.5 mg at bedtime with a goal dose of 1 mg twice daily to a maximum of 1 mg three times daily. Case reports describe a positive response from the clonidine patch as well. The onset of therapeutic effects for both clonidine and guanfacine is slow, ranging from 2 weeks to a few months.[40,43]

Dopamine-blocking antipsychotic drugs (haloperidol, fluphenazine, pimozide, and risperidone) are the most effective drug treatment options for managing motor and vocal tics associated with Tourette's disorder, but they carry the risk of extrapyramidal side effects.[40,41,43] A controlled trial showed risperidone 3.8 mg/day was more effective than pimozide 2.9 mg/day and was associated with fewer extrapyramidal side effects.[44] A Cochrane database review of pimozide for Tourette's disorder showed it was slightly less effective than haloperidol but comparable in efficacy to risperidone.[45] Uncontrolled data show benefit from olanzapine, ziprasidone, and aripiprazole. All have sufficient dopamine type 2 (D_2) blockade to exert therapeutic benefit.[40,43,46]

Therapy with risperidone, pimozide, or haloperidol should be initiated at very low doses of 0.25 to 0.5 mg/day given at bedtime and then increased gradually. Gradual titration over 2 to 3 weeks helps minimize extrapyramidal and sedative effects while permitting careful assessment of response. Symptoms can regress within 48 to 72 hours after an effective dose is reached. Doses less than 5 mg/day are effective in controlling tics for most patients.[40,41,45,]

CLINICAL CONTROVERSY

The decision to treat Tourette's disorder with a D_2 receptor antagonist (atypical or conventional) rather than an α_2-agonist is controversial and can be challenging. The choice is usually based on whether high efficacy (D_2 antagonist) or milder adverse effect burden (α_2-agonist) is more desirable in an individual patient.[3,40,43]

COMORBIDITY

Pharmacotherapy of Tourette's disorder is challenging because of the common occurrence of coexisting disorders typically requiring medication combinations. Often the behavioral problems precede and are more disturbing than the involuntary movements, making them a treatment priority.[40–42]

TOURETTE'S AND ADHD

Pharmacotherapy with stimulants increases dopaminergic and noradrenergic activity, which has the potential to aggravate or precipitate tics, although short- and long-term studies in 71 children showed no worsening of tics with methylphenidate dosed up to 0.5 mg/kg/day.[3] Studies examining the comparative effects of methylphenidate and dextroamphetamine on tics in children found the majority experienced improvement in ADHD symptoms with acceptable effects on tics. Methylphenidate was better tolerated than dextroamphetamine.[3,40]

A double-blind, placebo-controlled trial compared methylphenidate or clonidine monotherapy to combination methylphenidate and clonidine in patients with ADHD and Tourette's disorder. Combination therapy demonstrated the greatest benefit in reducing symptoms of ADHD and tics (P <0.0001).[3] Clonidine appeared most helpful for impulsivity and hyperactivity, whereas methylphenidate was most helpful for inattention. All treatments were well tolerated, but sedation was common (28%) in those receiving clonidine.[3] Patients and caregivers should be aware of the risks of using stimulants in children with Tourette's disorder (see ADHD section); careful monitoring is essential.[3,40]

A controlled trial of atomoxetine versus placebo in 117 children with ADHD and Tourette's disorder over 18 weeks showed treatment with atomoxetine 0.5 to 1.5 mg/kg/day improved symptoms of both, with overall good tolerability. Treatment-emergent nausea, decreased appetite, decreased body weight, and increased heart rate occurred significantly more often in those receiving atomoxetine compared with those receiving placebo.[3]

Clonidine or guanfacine alone are less effective alternatives to stimulants in the treatment of children with Tourette's disorder and ADHD. Guanfacine was administered to 34 children (mean age 10.4 years), with ADHD and tic disorder during an 8-week placebo-controlled trial at a dose of 1.5 to 3 mg/day. Tic severity decreased by 31% in the guanfacine group compared to 0% in the placebo group.[3] There was a mean improvement of 37% on the teacher-rated ADHD scale compared with 8% improvement with placebo. Because of its similarity to clonidine, guanfacine's cardiovascular effects warrant careful clinical monitoring.[3,4,6]

Results from these studies concur with the Texas Children's Medication Algorithm for ADHD, which recommends a stimulant (preferably methylphenidate) or atomoxetine as first-line treatment for ADHD in children with Tourette's disorder or chronic tics.[6]

TOURETTE'S AND ANXIETY OR MOOD DISORDERS

Therapeutic trials (6–12 weeks) of a selective serotonin reuptake inhibitor (SSRI) or clomipramine should be added to tic-specific therapy when obsessive-compulsive, anxiety, or depressive symptoms cause functional impairment in patients with Tourette's disorder.3,[40,41] Careful monitoring for behavioral activation, disinhibition, and motor restlessness is essential during SSRI or clomipramine therapy, because these symptoms can indicate increased risk for suicidal behavior or a switch to mania, requiring drug discontinuation.[3,32]

ADJUNCTIVE OR ALTERNATIVE TREATMENTS

For those who are unresponsive, partially responsive, or unable to tolerate dopamine antagonists or α_2-agonists, several adjuncts or alternative treatments are available. Clonazepam, topiramate, and baclofen appear to offer promise in relieving tics and associated symptoms.[40,43] Extensive clinical experience with the dopamine-depleting drug tetrabenazine shows improvement in motor and vocal tics, but controlled trials are needed.[40] Seven patients with antipsychotic-resistant tics and antibodies to caudate nucleus protein received single transfusions of immunoglobulin, which caused remission of motor and vocal tics for more than 6 months.[47] Botulinum toxin injected into the vocal cords has improved severe

vocal tics in case reports, but it requires further study.[40] For truly severe and refractory cases, deep brain stimulation and even neurosurgery have been effective.[40] Nonpharmacologic interventions include support groups and "habit-reversal therapy."[48] Further information for patients, families, and educators is available on the Tourette's Syndrome Association website (http://www.tsa-usa.org).

ADVERSE EFFECTS

For clonidine and guanfacine, the most common adverse effect is sedation. Fortunately, tolerance usually develops to this effect over days to weeks. The most potentially serious side effects are cardiovascular (see the section on ADHD).[3,35] Other α_2-agonist side effects are dry mouth, constipation, headache, mood changes, and even a temporary worsening of tics in ~10% of patients.[3,43]

Atypical antipsychotics (e.g., risperidone, olanzapine, ziprasidone, and aripiprazole) pose similar adverse effect risks in children and adolescents compared with adults (see Table 72–4).[31,46] Available data show that children and adolescents are at higher risk for experiencing sedation, acute extrapyramidal side effects, hyperprolactinemia, withdrawal dyskinesia, and significant weight gain during treatment compared with adults. Risperidone is associated with more weight gain in youths than adults, and ziprasidone and aripiprazole do not seem to be as "weight neutral" in pediatric populations as in adults.[20,31] Ziprasidone carries a risk of QTc prolongation, although torsades de pointes has not been reported, and the clinical significance requires further study.[20,28,43]

6 Adverse effects have been reported with haloperidol doses of 2 mg/day or greater. In one review of 24 patients treated with haloperidol for Tourette's disorder, 66.7% discontinued treatment because of intolerable side effects (e.g., dysphoria, akathisia, nervousness, sedation, dystonia, and cognitive dulling or feeling drugged).[49] Lowering the dose can alleviate side effects. An antiparkinsonian agent such as benztropine (at a starting dose of 0.5 mg orally twice daily) sometimes will reverse extrapyramidal side effects. Whether a patient with Tourette's disorder is developing a new tic or tardive dyskinesia can be difficult to determine.[3,40,43]

Pimozide is less likely to cause extrapyramidal side effects than haloperidol.[45] Anticholinergic side effects can occur in addition to drowsiness, and, occasionally, anxiety will occur. ECG changes, including T- and U-wave abnormalities and prolongation of the QTc interval, are found rarely with recommended therapeutic doses of pimozide for Tourette's disorder; however, drugs that inhibit CYP3A4 (e.g., clarithromycin and fluoxetine) should not be combined with pimozide because of the risk of excessively elevating pimozide blood levels, which can result in lethal QTc prolongation.[6,40]

PHARMACOECONOMIC CONSIDERATIONS

Haloperidol provides the most economic drug therapy because of high efficacy and low cost. Pimozide and atypical antipsychotics are more expensive than generic haloperidol, and they require ECG and metabolic monitoring, respectively. Although generic clonidine is inexpensive, delayed onset of effect and significantly lower efficacy substantially increase total costs of treatment.

EVALUATION OF THERAPEUTIC OUTCOMES

An adult outcome study involving 58 subjects with Tourette's disorder found that 40% were currently taking medication for their symptoms. The most frequently taken medications were antipsychotics (50%), antidepressants (36%), and clonidine (23%). Anticholinergic drugs, stimulants, and benzodiazepines were used by less than 10% of patients.[42] Evaluating therapeutic interventions is challenging, as most patients can suppress their tics voluntarily for minutes to hours.[43] Also, numerous factors, such as stress, concentration, and relaxation, can affect tic frequency and severity. The use of regular videotaped assessments in conjunction with standardized rating scales (Yale Global Tic Severity Scale) is helpful in objectively evaluating symptoms, side effects, and overall drug response.[40–42]

6 Individuals with Tourette's disorder are particularly sensitive to medication side effects, so medication dosing must be individualized with low starting doses and careful weekly titration to response, realizing that it can take 1 to 2 months for an adequate therapeutic trial. Children taking any dopamine-blocking medication should receive monitoring every 3 to 6 months for extrapyramidal effects and tardive dyskinesia with a standardized rating scale (e.g., Abnormal Involuntary Movement Scale [AIMS]).[31] Patients given pimozide or ziprasidone should receive baseline and follow-up ECGs.[31,43] Consult the ADHD section for additional monitoring recommendations for atypical antipsychotics.[40,42,43]

CONCLUSION

In summary, haloperidol, pimozide, and risperidone have the advantages of greatest efficacy and rapid onset in the treatment of Tourette's disorder. Ziprasidone, olanzapine, and aripiprazole show promise; however, comparison studies with haloperidol, pimozide, and risperidone are needed to determine their relative safety and efficacy. Clonidine and guanfacine have the advantage of causing no extrapyramidal side effects, but they are significantly less effective and require ongoing cardiovascular monitoring. Drug treatment must be highly individualized, considering comorbid disorders, side effect sensitivity, and drug interactions.

ENURESIS

The essential feature of enuresis is repeated involuntary or inappropriate voiding of urine by day or night that is not caused by a general medical condition.[1]

ETIOLOGY, PATHOPHYSIOLOGY, AND CLINICAL PRESENTATION

Medical causes of inappropriate voiding (e.g., diabetes mellitus, diabetes insipidus, seizure disorders, and urinary tract infections) should be ruled out.[50,51]

CLINICAL PRESENTATION OF ENURESIS

General

- Patients are 5 years old or older.

Symptoms

- Patients repeatedly void urine into bed and/or clothes involuntarily or intentionally.
- There is either a frequency of twice weekly for at least 3 consecutive months or the presence of clinically significant distress or impairment in social, academic (occupational), or other area of functioning.

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 4th ed. Text rev. Washington, DC: American Psychiatric Association 2000:39–134.

Enuresis occurs in 12% to 25% of 4-year-olds, 7% to 10% of 8-year-olds, and 2% to 3% of 12-year-olds, with 1% to 3% continuing to experience enuresis in late teenage years.[50] After age 5 years, there is a 15% annual rate of spontaneous remission. The ratio of males to females with enuresis is 2:1.[50] Factors that predispose a child to enuresis include a positive family history, institutionalization, low socioeconomic status, reduced functional bladder capacity, delayed or lax toilet training, constipation, psychological factors, and developmental delay.[50] Some children with nocturnal enuresis lack the normal circadian variation in urine excretion rate, urine osmolality, and antidiuretic hormone (ADH) secretion. Nocturnal enuresis is not associated with a particular sleep stage, although children with enuresis can be more difficult to arouse.[50]

TREATMENT

The first steps in treating a child with enuresis are to educate the family about the high frequency of the problem, dispel any misconceptions, provide emotional support, and strongly discourage punishment.[51]

7 Continence skills and various behavioral and conditioning methods remain the primary treatments for enuresis, and drug treatment remains a secondary approach.[50,51] Simple behavioral and physical interventions such as encouraging voiding at least once every 2 hours and having the child drink liberal fluids throughout the day with minimal fluids after 6 P.M. can decrease enuresis without any side effects or safety concerns.[51] Complex interventions, such as dry-bed training in combination with bed-wetting alarms, can be tried but require time and effort. There is insufficient evidence to support complex interventions without an alarm. After 3 to 4 months of using a bed-wetting alarm, enuresis is cured in two-thirds of children.[50,51]

Alarms are more effective than pharmacotherapy with longer lasting results, although medications work faster, within 2 weeks. Combining medications and alarms has been tried with mixed results.[50,51] Desmopressin tablets are preferred to TCAs (e.g., imipramine) because of greater efficacy and lower toxicity risk.[50,51] Oxybutynin and tolterodine may be effective adjuncts to desmopressin in partial responders, but they are not as effective as monotherapy.[50–52]

DESMOPRESSIN

8 Desmopressin acetate, a synthetic analogue of the natural human ADH arginine vasopressin, is currently available in a nasal spray, which is no longer recommended, and a more widely used oral tablet for the treatment of nocturnal enuresis.[50,51] Desmopressin increases overnight urinary osmotic concentration by increasing water reabsorption and reducing the volume of urine entering the bladder.[50,51] It is effective in reducing the number of wet nights in 10% to 65% of children within 1 to 2 weeks, with cessation of bed-wetting in up to 48% of children; however, up to 80% relapse upon discontinuation.[50,51]

In a 6-month, randomized, controlled trial comparing desmopressin (200–400 mcg), imipramine (25 mg), and combination desmopressin (200 mcg) and oxybutynin (5 mg) in 145 enuretic children (mean age 7.8 years), the combination produced the most rapid results, although the number of wet nights per month at 6 months was similar in the combination desmopressin/oxybutynin group (3.7 ± 5.4) compared with the desmopressin monotherapy group (4.0 ± 4.6). Both treatments were superior to imipramine (9.3 ± 8.3). The mean number of wet nights during the 2-week baseline period in all groups was 13. Tolerability was superior in the desmopressin groups compared with the imipramine group.[52]

Intranasal desmopressin should not be used because of the unacceptable risk of hyponatremia, which may cause seizures. Only the tablet form is approved by the FDA for primary nocturnal enuresis. For children 6 years of age or older, desmopressin tablets can be initiated at 200 mcg at bedtime. Approximately 1% of oral desmopressin is absorbed. Plasma concentrations reach a maximum approximately 45 minutes after administration. Effective dosages range from 200 to 600 mcg/day of oral desmopressin. The duration of action varies from 10 to 20 hours, and there is compensatory polyuria the following day when the drug wears off.[50,51]

TRICYCLIC ANTIDEPRESSANTS

8 Imipramine is the most studied TCA, although desipramine, amitriptyline, and nortriptyline are also effective. Imipramine is effective in increasing dry nights for up to 60% of individuals, with cessation of bed-wetting in only ~20% of children.[50,51] The mechanism of action of TCAs in treating enuresis is unknown.[50,51] For children 6 years of age and older, the usual starting dose is 25 mg given 30 minutes before bedtime. Doses can be increased by 25 mg weekly until response is achieved. The usual effective dosing range is 1 to 2.5 mg/kg/night, and doses should not exceed 2.5 mg/kg/night. Most children respond within the first week.[50] Because of the risk of toxicity and death in overdose, the International Children's Continence Society recommends that TCA be used only when all other therapies have failed.[51]

ADVERSE EFFECTS

Desmopressin tablets can cause transient headache, chills, dizziness, nausea, and abdominal pain. Rarely, water intoxication, hyponatremia, and subsequent tonic-clonic seizures have been reported.[50,51] From 1972 to 2005, 151 postmarketing cases of hyponatremia were reported in children with nocturnal enuresis, of whom 145 were treated with intranasal desmopressin, and 6 received tablets. When desmopressin is administered, evening fluids should be restricted 1 hour before and 8 hours after drug administration. Desmopressin tablets should be stopped during acute illnesses that may lead to fluid or electrolyte imbalance. Prompt medical assessment is needed if headache, nausea, or vomiting develops, as these could be signs of hyponatremia. Concomitant medications that may lower sodium (e.g., antidepressants and oxcarbazepine) or illnesses that change hydration status (e.g., the flu) can increase the risk of hyponatremia.[50,51]

Adverse effects of TCAs are dose related and include sedation, dizziness, dry mouth, constipation, and weight gain, along with the risk of ECG changes, heart block, and lowering of the seizure threshold.[32,51]

PHARMACOECONOMIC CONSIDERATIONS

No pharmacoeconomic studies on enuresis are available. The use of a bed-wetting alarm provides the highest overall cure rate, and drugs are a secondary approach. Several types of reusable bed-wetting alarms are available, ranging from $30 to $170 per alarm, as opposed to $90 to $130 for a 30-day supply of desmopressin.[53] However, insurance companies commonly reimburse drug therapy, whereas most do not reimburse for alarms. Therapy with desmopressin is substantially more expensive than with TCAs because of higher cost.

EVALUATION OF THERAPEUTIC OUTCOMES

An accurate baseline of bed-wetting frequency must be established. A 50% or greater increase in dry nights is considered a therapeutic response. For example, if baseline dry nights are 2 out of 7 days per

week, and drug treatment results in 4 or more dry nights per week, the drug is considered effective. If only one more dry night per week occurs, and the drug is at the low end of the dosing range, a dosage increase is needed.[50,51]

At least 1 week is needed to evaluate the efficacy of TCAs, and 2 weeks can be needed for evaluation of desmopressin. If drug treatment is ongoing for several months, particularly if enuresis has resolved, attempts to discontinue the drug every 3 to 6 months are recommended to assess for spontaneous remission. Slow tapering of the medication can decrease the frequency of relapse. Unfortunately, therapeutic drug efficacy does not extend beyond drug discontinuation.[50,51]

CONCLUSION

Initially, simple interventions such as lift and awaken can be implemented. A bed-wetting alarm in combination with complex behavioral interventions provides lasting cures for two-thirds of children. Drug therapy has the advantage of more rapid results, but relapse is high upon drug discontinuation.[50,51] Desmopressin tablets are preferred to imipramine because of better tolerability and safety.[47,48]

ABBREVIATIONS

ADH: Antidiuretic hormone

ADHD: Attention deficit/hyperactivity disorder

CHAPTER 73

Eating Disorders

STEVEN C. STONER

KEY CONCEPTS

1. Clinicians who specialize in the treatment of eating disorders feel that anorexia nervosa, bulimia nervosa, and eating disorders not otherwise specified should be commonly accepted as serious mental illnesses.
2. Because the causes of eating disorders are complex, multidisciplinary treatment, including pharmacologic and nonpharmacologic interventions, are preferred to ensure a positive outcome. Although outpatient treatment is appropriate for the majority of patients, it is important to recognize the factors that indicate a need for inpatient treatment.
3. Careful medical and psychiatric assessments are needed at baseline to determine the severity of illness and the complexity of comorbid conditions.
4. In patients with anorexia nervosa, one goal is to achieve and maintain a body weight within 85% of the normal weight for age and height. If the patient is malnourished, oral refeeding with the daily caloric intake starting at 1,000 to 1,600 calories per day (4186 to 6697 J/day) and slowly titrating to 2,000 to 3,000 calories per day (8372 to 12,557 J/day) is preferred. Parenteral refeeding is a treatment of last resort.
5. Antidepressants are considered to be ineffective for the core symptoms of anorexia nervosa and are reserved for patients with mood, anxiety, and obsessional symptoms that persist after weight has improved.
6. Antidepressants can improve both mood and specific target symptoms in bulimia nervosa, but they remain adjunctive to nonpharmacologic treatments.
7. Selective serotonin reuptake inhibitors are first-line agents when medications are indicated for bulimia nervosa. Compared with other antidepressant classes, they have improved tolerability and safety, although superior efficacy has not been studied. The dose of fluoxetine in bulimia nervosa is higher (60 mg/day) than the dose usually used in depression.
8. An adequate drug therapy trial in bulimia nervosa is 4 to 8 weeks. If drug treatment fails, consider that the patient may be vomiting or using other purging methods affecting the absorption of the drug.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

9. The optimal duration of antidepressant treatment for bulimia nervosa is unknown, but most clinicians continue them for 9 to 12 months in patients who respond and then reevaluate the need for ongoing medication management.

1 The American Academy for Eating Disorders has taken the firm public stance that eating disorders are and should be classified as serious mental illnesses.[1] The spectrum of eating disorders encompasses several complex diseases, sharing the pathologic feature of overevaluation of body shape and weight. Eating disorders arise from the interaction between environmental, societal, developmental, psychosocial, genetic, and biologic factors. It is estimated that 5 to 10 million women and 1 million men in the United States alone have an eating disorder. The urbanization of society, social pressure, and obsession with perfection and being thin have led to an increasing prevalence of eating disorders, with the peak onset being between 16 and 20 years of age.[2–5] Anorexia nervosa, bulimia nervosa, and eating disorders not otherwise specified (EDNOS) are the primary disorders that have been identified.[6–10]

Despite an improved understanding of these cognitively and emotionally disabling and potentially fatal disorders, management remains difficult. Pharmacologic intervention is a small part of a comprehensive plan that emphasizes cognitive behavioral therapy (CBT) and psychotherapy.

EPIDEMIOLOGY

ANOREXIA NERVOSA

Anorexia nervosa occurs predominantly in girls and young women (90%) and usually presents in late adolescence (median onset 17 years of age), with new cases rarely diagnosed after age 40. The estimated prevalence of the disorder in the general population is 0.3% of females; however, a subthreshold level of symptoms is estimated to affect 0.37% to 1.3% of the population.[3,11–13] Longitudinal management of anorexia nervosa is difficult, even in cases where weight restoration is achieved. Rates of relapse requiring hospitalization within 1 year are estimated to exceed 30%.[14]

The promotion of the virtues of being thin is also a potentially negative environmental factor. Many websites, for example, inappropriately promote healthy lifestyle aspects of anorexia and being thin as a means of being in control, successful, and coping with life's pressures.[15]

BULIMIA NERVOSA

Bulimia nervosa also occurs predominantly in girls and young women (90%) and usually presents in adolescence or early adult life.[6]

Between 1% and 4.6% of adolescent and young adult females meet the diagnostic criteria for bulimia.[4,11,16,17]

EATING DISORDER NOT OTHERWISE SPECIFIED

EDNOS is also described in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision; *DSM-IV-TR*).[4,16] Originally designed to capture eating disorder cases that did not meet diagnostic criteria of anorexia or bulimia, it has instead developed into a diagnosis of indifference. Its prevalence is estimated at 1% to 4.7% of the population, and up to 50% of patients with an eating disorder admitted to tertiary care settings are believed to have this condition.[11,18] These individuals present with symptoms characteristic of eating disorders but do not meet specific diagnostic criteria. Two examples of EDNOS are night eating syndrome (NES) and binge eating disorder (BED).

NES is most common in obesity clinic populations, often accompanied by depressive symptoms. The syndrome is defined by early morning anorexia, hyperphagia in the evening, nighttime insomnia, and subsequent early morning awakening.[10,19,20] NES affects an estimated 1.5% of the general population and 8.9% to 27% of patients in obesity clinics.[21–23] Patients with NES are reported to benefit from antidepressant therapy, most notably sertraline 50 to 200 mg daily.[10]

Although part of the EDNOS classification, BED continues to be classified as a research diagnosis. The diagnostic criteria for BED describe recurrent episodes of binge eating without compensatory behaviors (e.g., purging, excessive exercise, or fasting). BED typically presents later in life (older than 40 years of age), and approximately one-fourth of BED patients are male.[18,24]

ETIOLOGY AND PATHOPHYSIOLOGY

2 The potential etiologic or exacerbating factors for eating disorders encompass physiologic, biochemical, developmental, genetic, psychosocial, and psychiatric phenomena. The biologic basis for eating disorders is difficult to delineate because it is unclear if the biologic changes are caused by or are a result of the aberrant eating behavior.

Abnormalities of the hypothalamic-pituitary-gonadal, hypothalamic-pituitary-adrenal, and hypothalamic-pituitary-thyroid axes are described as potential causes of anorexia nervosa. Amenorrhea is found in the majority of females with anorexia, providing support for the association with gonadotropin.[17] However, symptoms related to these abnormalities do not always correct with weight normalization, suggesting a primary biologic abnormality.[24]

The roles of serotonin, norepinephrine, and dopamine have been studied extensively, as these neurotransmitters have important functions in controlling eating behaviors. Dysfunctions in these systems are thought to be secondary to weight loss. Some aspects of serotonin function do remain abnormal after weight restoration, suggesting that other mechanisms are involved.[25,26] Another molecular genetic target of study is brain-derived neurotrophic factor (BDNF), which is also being studied in disease states such as depression.[27]

Strong genetic influences are present in anorexia and likely play a role in both bulimia and BED, independent of the presence of obesity.[28] Twin studies have shown concordance of ~55% and 35% in monozygotic twins and 5% and 30% in dizygotic twins for anorexia and bulimia, respectively. Genetic mutation studies have focused on polymorphisms of the serotonin 2A receptor, with mixed preliminary results.[24] One acquired hereditary abnormality being studied is the presence of low-function alleles associated with the serotonin transporter (*5-HTTLPR*) and serotonin 2A receptor gene (*−1438G/A*), as findings suggest an association with poor treatment response.[29]

Emphasis is also placed on social stress and psychological and developmental issues related to dysfunctional family relationships triggering abnormal eating behavior.[4,17,18,30] Athletes are at risk for eating disorders, especially female gymnasts, ballet dancers, figure skaters, distance runners, swimmers, male wrestlers, and body builders.[31]

DIAGNOSTIC CRITERIA AND CLINICAL PRESENTATION

3 Anorexia and bulimia occur together in ~30% to 64% of patients with eating disorders and may not be distinct diagnostic entities, but rather a continuum of symptoms. Thus, careful medical and psychiatric assessment at baseline is essential.[32–34] Many patients initially present with either anorexia or bulimia and alternate from one to the other. Figure 73–1 demonstrates similar and unique features of both disorders.

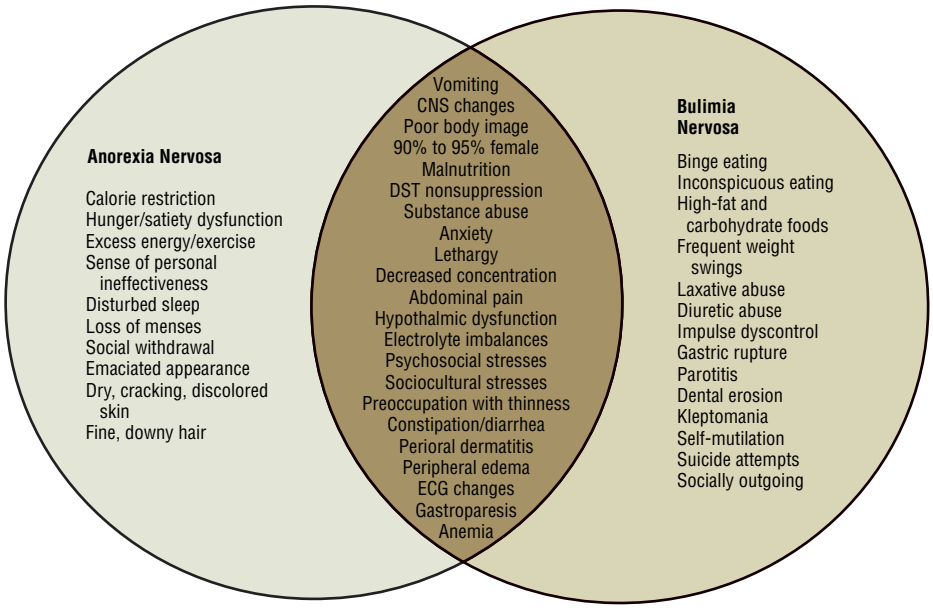

FIGURE 73-1. Signs and symptoms of anorexia nervosa and bulimia nervosa. (DST, dexamethasone suppression test; ECG, electrocardiogram.)

The use of purging methods is not limited to bulimia. Self-induced vomiting is the most common form of purging behavior.[35] Laxative abuse is another form common in both anorexia and bulimia, used by an estimated 3% to 70% of patients.[35–37] Although ineffective as a weight-loss strategy, laxative abuse is often used in combination with other behaviors, including exercise, diuretics, enemas, and saunas. Within the diagnostic framework of anorexia, laxative abuse is most common in those identified with the purging subtype.[35] Psychiatric symptoms of depression, anxiety, and borderline personality disorder are also reported in those who abuse laxatives.[35–37]

Depression, schizophrenia, obsessive-compulsive disorder (OCD), and conversion disorders should be included in the differential diagnosis of anorexia and bulimia, as eating abnormalities can be a component of these illnesses. The salient differences are the overriding drive for thinness, disturbed body image, increased energy directed at losing weight, and binge eating episodes that are relatively specific for eating disorders. Most patients with eating disorders experience relief of psychiatric symptoms on refeeding.[18]

ANOREXIA NERVOSA

The core features of anorexia are refusal to maintain a minimal normal body weight (e.g., greater than 85% normal body weight or body mass index [BMI] greater than 17.5 kg/m^2) and failure to make expected weight gains, intense fear and obsession about weight gain or being "fat," distorted body image, and amenorrhea for at least three consecutive cycles. Patients typically lack an appreciation for the degree of weight loss experienced or are preoccupied with the idea that a part of their body is too large, despite evidence to the contrary. The *DSM-IV-TR* further classifies anorexia nervosa as restricting type (failure to engage in binge eating or purging behavior) or binge eating/purging type, in which patients regularly participate in bingeing or purging.[16] The anorexic patient has difficulty sensing when he or she is full (satiety) and commonly complains of feeling bloated after eating. Patients also describe not feeling in control of various aspects of their life, particularly caloric intake. Anorexic patients often present with features of major depression, but these symptoms should initially be considered to be secondary to starvation and not a true mood disorder.

Several proposed changes for the not yet released fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* are being considered. These include the potential elimination of the amenorrhea diagnostic component and elimination of the subclassifications of anorexia nervosa.[38]

CLINICAL CONTROVERSY

Many thought leaders believe the diagnostic criteria for anorexia nervosa are too complex and that some actual eating disorders do not fully meet the DSM-IV-TR criteria. Potential changes to the diagnostic criteria are being considered for the yet to be released DSM-V.

Psychiatric comorbidity is common, as up to 75% of patients have a primary mood disorder.[39] There is also a link between anorexia and personality disorders and anxiety disorders, such as social phobia and OCD.[40] The lifetime prevalence of OCD in patients with anorexia nervosa is reported to be as high as 40%; the lifetime prevalence in the general population is 2.5%.[39–41] The impact that psychiatric comorbidity has on treatment outcomes of anorexia is unknown but is likely dependent upon the severity of the comorbidity itself. It is important to understand that deprivation of food may contribute to both mood and cognitive fluctuation.[42]

CLINICAL PRESENTATION OF ANOREXIA NERVOSA

General

- Patients refuse to maintain body weight and have distorted perceptions about their body.

Symptoms

- Patients have obsessions and fears about eating and gaining weight.
- They complain about feeling full even when they have eaten very little food.
- Denial of symptoms and low self-esteem are the norm. Patients often feel ineffective and have a lack of self-control.

Signs

- Weakness, lethgy, cachexia, amenorrhea, vomiting, restricted food intake, inappropriate exercise, delayed sexual development, edema, delayed gastric emptying, constipation, bradycardia, hypotension, osteoporosis, dry cracking skin, lanugo, callus on dorsum of hand, perioral dermatitis, erosion of dental enamel

Laboratory Abnormalities

- Hypokalemia, hypokalemic alkalosis, hypomagnesemia, leukopenia, QT interval prolongation, ST segment depression, U waves, hypercholesterolemia, anemia

Other Diagnostic Tests

- Nonspecific electroencephalogram (EEG) changes

BULIMIA NERVOSA

The core feature of bulimia nervosa is recurrent episodes of binge eating (an excessive intake of calorie-laden food over a short period of time). Persons with bulimia are overly sensitive about their weight and have a distorted body image. Most have normal weight, although they might fluctuate between being underweight and overweight. Patients lack control over their eating and participate in recurrent compensatory behavior to prevent weight gain. These behaviors may include self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; strict dieting or fasting; or excessive exercise. To meet *DSM-IV-TR* criteria, the binges and compensatory behaviors must occur on average at least twice weekly for 3 months. Bulimia can further be differentiated by purging type (regularly engages in self-induced vomiting or the misuse of laxatives, diuretics, or enemas) or nonpurging type (uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but does not engage in purging activities).[16]

CLINICAL PRESENTATION OF BULIMIA NERVOSA

General

- Patients binge eat and stop when they have abdominal pain or self-induced vomiting or are interrupted by another person.

- They have a pattern of severe dieting followed by binge eating episodes.
- They are concerned about their body image but do not have the drive to thinness, which is characteristic of anorexia nervosa.

Symptoms

- Patients do not eat regular meals and do not feel satiety at the end of a meal.
- They may use laxatives for weight control.
- They have guilt, depression, and self-disparagement after binges.
- Social isolation can result from frequent bingeing.
- Chaotic and troubled personal relationships and substance abuse are common.

Signs

- Bingeing, vomiting, salivary gland inflammation, erosion of dental enamel, callus on dorsum of hand, perioral dermatitis, dental caries, parotid gland enlargement, abdominal pain, upper end of normal body weight or slightly overweight, frequent weight fluctuations, diminished masticatory ability

Laboratory Abnormalities

- Hypokalemia, hypochloremic metabolic acidosis, elevated serum amylase

Other Diagnostic Tests

- None

Under consideration for *DSM-V* is the potential standardization of the frequency of symptoms for bulimia and BED by reducing the requirement from two to one time per week for 3 consecutive months and also eliminating the subclassifications of bulimia nervosa.[38]

CLINICAL CONTROVERSY

Bulimia nervosa involves extensive binging and purging behaviors. New diagnostic considerations are being considered for DSM-V which would reduce the frequency of binging episodes necessary to establish the diagnosis of bulimia nervosa.

Patients typically binge and vomit at least once daily. Caloric intake varies, but patients can consume between 5,000 and 20,000 calories (20,929 and 83,716 J) during a single binge. Patients tend to consume foods that are easy to ingest, do not require much chewing or preparation, and are high in carbohydrates or fat. Binge eating is typically secretive and precipitated by a stressful event, followed by postbinge remorse. Binges often last less than 2 hours but can extend to more than 8 hours. To compensate for the excessive caloric intake, many patients fast for prolonged periods, exercise compulsively, purge, or abuse laxatives.

Psychiatric comorbidity includes depression (up to 80%), poor impulse control, and substance abuse. Approximately 30% to 37% of bulimic patients have a personal history of substance abuse.[43] Kleptomania and borderline and avoidant personality disorders are also frequently observed.[40,42,44] Patients also commonly steal laxatives and comfort items, such as candies and clothes.[17]

BINGE EATING DISORDER

Patients with binge eating disorder present with recurrent episodes of bingeing without the compensatory behaviors associated with anorexia or bulimia. It is estimated that 5% to 10% of patients seeking treatment for obesity have BED. Comorbid psychotic disorders are common and reported in >70% of BED patients.[45] Major depressive disorder and low self-esteem are common, although the self-deprecating focus on body image is less severe than in anorexia or bulimia.[22,41] Diagnostic criteria require that episodes of bingeing occur at least twice weekly over a period of 6 months.[16]

For the *DSM-V,* there may be standardization of frequency and time frame for compensatory behaviors as well as adding BED as a formal diagnosis.[38]

MEDICAL COMPLICATIONS OF EATING DISORDERS

The potential medical complications of eating disorders involve multiple organ systems. The type of medical complication encountered is dependent on the type and frequency of the eating disorder behavior. Cardiac complications may occur and can include wasted cardiac muscle, orthostatic hypotension, decreased cardiac output, arrhythmia, and QTc interval prolongation.[46] During caloric restoration, there is a potential risk for developing fatal cardiovascular collapse known as refeeding syndrome. This risk is reduced by the gradual versus rapid reintroduction of calories.

Metabolic (metabolic acidosis, metabolic alkalosis) and electrolyte disturbances (e.g., hypokalemia, hypomagnesemia, and hypocalcemia), and dehydration are often seen. Elevations in bicarbonate levels during periods of hypokalemia can be an indication that the patient is inducing vomiting or using dietary weight loss medications. Non-anion-gap acidosis has also been reported with the abuse of laxative agents. Additionally, both acute and chronic renal failure has been reported.

Gastrointestinal (GI), oropharyngeal, and dental complications are frequent, as are general complaints of lethargy and fatigue.

Hormonal changes related to the hypothalamic-pituitary-gonadal axis resulting from starvation are seen. These abnormalities include effects on estradiol, the gonadotropins (e.g., luteinizing hormone, follicle-stimulating hormone, and gonadotropin-releasing hormone), thyroid function, adrenal function, and growth hormone.[17,46] Specific to female athletes is the female athlete triad, defined by the development of irregular menses, osteoporosis, and disordered eating.[46,47] Osteopenia, osteoporosis, and infertility are potential long-term complications of suppressed estrogen. The restoration of weight, specifically in anorexia nervosa, reverses the bone loss, although estrogen supplementation does not appear to be effective.[48] In all cases, the preferred method to address these issues is the normalization of nutrition. The impact on female fertility is not well studied, although the ability to carry a pregnancy to term or to give birth to a child of average birth weight appears reduced.

Chronic starvation can contribute to brain atrophy. Decreases in white matter and cerebrospinal fluid volumes return to normal after a healthy weight is achieved, but gray matter loss can persist.[18,49,50] A thorough physical and laboratory evaluation, as described in Table 73–1, is essential to determine the severity of medical complications.[16,30,51]

TABLE 73-1 Physical and Laboratory Assessment of Eating Disorders

Evaluation	Target Symptoms
Pulse	Bradycardia
Blood pressure	Hypotension, orthostasis
Height/weight	Underweight for size and age/body mass index
Respiratory rate	Rapid if heart failure occurs during refeeding
Temperature	Hypothermia, cold intolerance
Electrocardiogram	ST depression, flat T waves, U waves, increased QT interval, atrioventricular block
GI	Hypoactive bowel sounds, gastritis, abdominal distention
Skin	Dryness, scaling, lanugo, hair loss, calluses on fingers and hands
Menses	Amenorrhea
Complete blood count	Leukopenia, anemias, thrombocytopenia
Electrolytes	Hypokalemia, hypomagnesemia, hypo- or hyperphosphatemia
pH	Metabolic alkalosis (acidosis if laxative abuse)
Amylase	Elevated; pancreatitis rare
Liver	Hypoalbuminemia, γ-glutamyl transferase if alcohol abuse
Thyroid	Low to low normal, but not true disease
Cortisol	Elevated with lack of suppression on dexamethasone suppression test
Bone density	Osteoporosis

TREATMENT

EATING DISORDERS

DESIRED OUTCOMES

The goals for patients with eating disorders are to reduce distorted body image; restore and maintain healthy body weight; establish normal eating patterns; improve psychologic, psychosocial, and physical problems; resolve contributory family problems; enhance compliance; and prevent relapse.[18] Specific to BED is the additional goal of weight loss.

ANOREXIA NERVOSA

The long-term prognosis of patients with anorexia nervosa is not clear, as studies focus only on patients receiving treatment. The course of the disorder most commonly consists of a single episode with subsequent return to normal weight, although patients can still experience issues with disturbed body image, disordered eating, and other psychiatric problems.[18] Some patients experience an unremitting course leading to death, whereas others suffer episodically. It is estimated that less than 50% of anorexic patients recover, and 20% remain chronically ill despite weight normalization, return of menses, and improved eating behaviors.[52] The prognosis is more favorable with longer follow-up care and younger age of onset, whereas a poorer prognosis is associated with chronic illness, lower initial weight, poor family relationships, obsessive-compulsive personality symptoms, and the presence of bulimia or purging behavior.[24,52–54] Long-term follow-up shows high mortality rates, with 5% to 10% of anorexic patients dying, most often the result of cardiac arrest or suicide.[16,52]

BULIMIA NERVOSA

The prognosis of bulimia nervosa, although not well studied, appears to be better than that of anorexia. Patients with milder presenting symptoms who are treated as outpatients tend to do better, whereas those with electrolyte imbalances, esophagitis, dental caries, and salivary gland enlargement have a more complicated course.[17] A 6-year follow-up study of patients who received intensive treatment found that 60% had a "good" response.[53] It is important to note that even in cases in which patients respond, they continue to exhibit symptoms that wax and wane. Total absence of symptoms is an uncommon outcome, and residual symptoms predispose the patient to relapse. The actual definition of recovery varies, as once-a-month binge–purge episodes are considered by some to be recovery if their episodes were previously more frequent, whereas other clinicians consider a patient recovered only when there is complete absence of these behaviors.[54]

GENERAL APPROACH TO TREATMENT

Treatment plans are individualized based on the severity of specific core features of the eating disorder and comorbid medical and psychiatric conditions. Psychiatrists, physician assistants, nurses, nutrition specialists, psychologists, and pharmacists play a role in the care of these complex patients. The absence of an adequate support system of family and friends can contribute to failed treatment. A critical first step is to determine the severity of illness, as that drives both the intensity and the setting for delivery of care. Hospitalization is based on the criteria outlined in Table 73–2 and is limited to only the most severely ill patients.[24,30,31] Medications are rarely indicated as a sole treatment for eating disorders, and many patients refuse medication, although they remain part of the comprehensive treatment strategy.[55–57] Comparative, double-blind, placebo-controlled trials are sparse, and most are limited by small sample sizes, ambivalent patient attitudes toward treatment, medical complications, and high dropout rates.[58]

TABLE 73-2 Criteria for Hospitalization of Patients with Eating Disorders

- Significant weight loss of 20% or more of normal weight, particularly if weight loss has been recent and rapid, severe starvation symptoms are present, or the patient has been ill for more than 2 years
- Reduced oral intake of food (sudden and persistent)
- Medical complications (e.g., edema) and metabolic abnormalities (e.g., hypoproteinemia) from bingeing, purging, and starvation (e.g., heart rate <40 bpm, blood pressure <90/60 mm Hg, glucose <60 mg/dL (<3.33 mmol/L), potassium <3 mEq/L (<3 mmol/L), or inability to maintain core temperature
- Co-occurring psychiatric symptoms, notably suicidal ideation, psychotic depression, or substance abuse and dependence
- Nonresponsive to outpatient treatment (after 3–4 months) and poor motivation to recover
- Demoralization or nonfunctional family
- Denial of severity of abnormal eating behaviors
- Continuous supervision required to prevent purging (vomiting or laxative abuse)

ANOREXIA NERVOSA

Nonpharmacologic Treatments

CLINICAL CONTROVERSY

Cognitive behavioral therapy and other nonpharmacologic interventions are generally considered preferred first-line treatment options for anorexia nervosa. Controversy exists as to what level of symptomatology should be present to consider the initiation of pharmacologic therapy.

Evidence supports that nonpharmacologic treatments have the greatest likelihood of eliciting a response in anorexic patients.[18,55] This includes CBT, behavioral management, interpersonal psychotherapy, nutritional counseling, and family therapy.[18,30,59] Current guidelines suggest at least 6 months of psychotherapy.[59] CBT helps the patient overcome distorted thinking, including self-worth as measured by body image, feelings of being fat despite evidence to the contrary, and denial. CBT also teaches patients how to use strategies besides eating to cope. Interpersonal psychotherapy focuses on interpersonal relationships and functioning, whereas CBT provides positive reinforcement for weight gain.[39] The benefit of treatment based on an addiction model (12-step program) is not supported by the literature.[18,24] Many psychiatric symptoms in an acutely ill patient, such as depression and anxiety, diminish or disappear with weight restoration. Initial treatment is directed toward restoring a healthy weight (greater than 90% of normal weight for age-matched controls) and treating food phobias.[60] After achieving medical stability and appropriate weight, therapy can be redirected toward addressing ongoing interpersonal problems, weight maintenance, cognitive restructuring, and skill development for relapse prevention.[61] Oral refeeding, initially with liquid formulas if necessary, is the most common approach to weight restoration.

4 In severe cases, nasogastric refeeding is preferred over Intravenous (IV) bolus dosing.[18] Total parenteral nutrition is reserved only for the management of severely malnourished patients and if other refeeding methods fail. The decision to administer total parenteral nutrition must be made carefully, because of the potentially devastating psychologic effect on patients who do not wish to gain weight.

Current clinical evidence suggests a controlled weight gain of 0.9 to 1.4 kg (2–3 lb) per week in inpatient settings and 0.2 to 0.5 kg (0.5–1 lb) per week in outpatient settings.[16,57,60] Recommendations vary; however, it is considered acceptable for patients to begin refeeding at 1,000 to 1,600 calories per day (4186 to 6697 J/day) (30–40 cal/kg/day [126–167 J/kg]) with slow titration upwards until they begin to demonstrate sustained weight gain.[18,59,62] This can require the intake of an additional 3,500 to 7,000 extra calories (14,650 to 29,301 J) per week.[59] Slow refeeding is important to minimize the risk of medical and psychologic consequences.[24]

Pharmacologic Therapy

Antidepressants Although many studies examine the role of antidepressants in the treatment of anorexia nervosa, they often have small sample sizes and large confidence intervals.[63] Antidepressants currently have no role in the acute treatment of anorexia, unless there is another clinical indication present.[18,24,55]

5 Data suggest that medication is ineffective if a patient weighs less than 85% of his or her expected weight. Thus, antidepressants should be initiated only if depression, anxiety, obsessions, or compulsions persist after the target weight is achieved.[24,60,64] The duration of treatment when antidepressants are used in this manner is unclear, but one study showed benefit in treated patients for 1 year, and current guidelines suggest 9 to 12 months of therapy.[4,18,59] Antidepressants, along with psychotherapy, have been used to help maintain weight and prevent relapse, but data supporting this are limited.[65] Most clinicians prefer the selective serotonin reuptake inhibitor (SSRI) antidepressants because they are better tolerated and have greater cardiovascular safety than tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs).[18,66] Because these patients are sensitive to anticholinergic and cardiovascular effects, if TCAs or MAOIs are used, low starting doses and slow titration toward an effective dose are appropriate. The risk of cardiotoxicity in a malnourished population must not be underestimated, and a baseline electrocardiogram (ECG) should be obtained before initiation of these agents.

Fluoxetine continues to be the most widely studied SSRI in anorexia. Most clinicians initiate at low doses, for example, 20 mg/day, and increase to a maximum of 60 mg/day based on response and tolerability.[62,63,65] Some clinical controversy exists regarding when antidepressant therapy should be initiated. During the starvation phases of anorexia, the majority of clinical trials suggest antidepressants are ineffective, and there is debate as to their effectiveness once weight restoration has occurred. Evidence from a 52-week, randomized, placebo-controlled clinical trial of 93 patients with the treatment arm receiving doses from 20 to 80 mg/day showed no difference between fluoxetine and placebo for time to relapse.[67]

Antipsychotics Typical antipsychotics were the first medications used to treat anorexia to reduce obsessive and paranoid thoughts about weight gain and anxiety and to promote weight gain.[68] However, there was little improvement, and the risks were considered to outweigh the benefits. Atypical antipsychotics have provided an additional alternative for treating anorexia. Most of the data are from case reports or small trials in both adolescents and adults using risperidone 0.5 to 1.5 mg daily, olanzapine 2.5 to 15 mg daily, and quetiapine 200 to 500 mg daily.[69–75] Improvement has been shown through weight increase and reduction of comorbid anxiety and depressive symptoms, but not all reports are favorable, and these agents require further study. Caution is urged in view of the report of increased QTc in an anorexic patient taking risperidone.[74] Optimal treatment duration is unknown, as most of the larger studies are less than or equal to 3 months in duration.

Miscellaneous Agents Metoclopramide can be helpful in reducing bloating, early satiety, and abdominal pain commonly found in anorexia, but it does not affect weight gain.[18] Low-dose, short-acting benzodiazepines (0.25 mg alprazolam or 0.5 mg lorazepam) given before meals are useful when severe anxiety limits eating.[18] Estrogen replacement has been used, but restoring menses through refeeding is a preferred approach to minimize bone density loss.

BULIMIA NERVOSA

Nonpharmacologic Therapy

The nondrug strategies used in bulimia are similar to those used with anorexia, and they are equally critical to success. CBT has the strongest evidence supporting its benefit in managing bulimia.[19,25] Current treatment guidelines suggest that CBT should consist of 16 to 20 sessions over a 4- to 5-month period.[59] Interpersonal psychotherapy also plays a role and has a moderate degree of evidence to support its use.[18,24] Nutritional counseling, planned meals, and self-monitoring can help interrupt the binge–purge cycle. Family therapy in bulimic patients is less critical than with anorexia, as these patients tend to be older. A recent study suggested that CBT-guided self-care was a more effective treatment approach in adolescents than family therapy, whereas other programs using self-help guides based on CBT have shown mixed results.[30,76] When such programs have been combined with medication, for example fluoxetine,

enhanced response has been reported.[77,78] Data support the use of 12-step programs, but they should not be used as monotherapy.[18,24]

Pharmacologic Therapy

Antidepressants Antidepressants are used in the acute and maintenance phases of bulimia adjunctively with nonpharmacologic approaches. A wide array of antidepressants, including TCAs, MAOIs, trazodone, serotonin-norepinephrine reuptake inhibitors (SNRIs), and SSRIs, have been studied. Additionally, several reviews analyzing this body of literature have been published, although there continues to be limited placebo-controlled, randomized, double-blind clinical studies.[24,55] Antidepressants are reported to reduce depression, anxiety, obsessions, and impulsive behaviors such as binge eating and purging, and improve eating habits, although their impact on body dissatisfaction remains unclear. The presence of comorbid mood disorders is not necessary for an antidepressant response.[24,79,80]

The benefit appears to be more robust in the acute phase of the illness, as relapse despite continued antidepressant use is common in patients who are in or near remission.[24,30,57] Antidepressant response usually occurs in 6 to 8 weeks, and reduction in frequency of binge–purge behavior has been as high as 73% and as low as zero.[55] Abstinence rates (elimination of bingeing and purging behaviors) with short-term use range from zero to 68%. More data are needed to determine the long-term benefits of antidepressants for preventing relapse of bulimia symptoms. One trial evaluating the impact of fluoxetine versus placebo in the maintenance phase showed a better outcome in patients receiving fluoxetine 60 mg/day, although high dropout rates in both groups blurred the overall benefit.[81]

7 SSRIs are the preferred agents because of their tolerability and because they have been studied in the largest number of patients. Fluoxetine remains the only medication with Food and Drug Administration (FDA) approval for bulimia. Tolerability is the primary criterion for selecting an antidepressant in the treatment of bulimia because of patients' heightened sensitivity to adverse effects and the lack of a clear difference in efficacy between the classes. Even though there is a suggestion that MAOIs produce the most robust effect, the risk of using these medications in impulsive patients limits their use.[57] SNRIs have shown promising results; however, the data supporting their use are limited to case reports.[82] Bupropion is not used in bulimic patients because of the increased risk of seizures.

Before initiating pharmacologic-based therapy, a careful baseline physical examination, ECG, and laboratory work-up are essential. Underlying ECG changes secondary to hypokalemia or bradycardia and atrioventricular block from starvation can be present. There is potential for fatal outcomes secondary to cardiac arrest or suicide. All antidepressants can cause seizures; thus, a careful risk–benefit assessment is warranted if the patient has predisposing factors such as a personal or family history of seizures, cerebrovascular disease, or alcohol or sedative-hypnotic withdrawal.

Doses in the treatment of bulimia nervosa are similar to those in patients treated for depression, though at the higher end of the range. Readers are referred to Chapter 78 for antidepressant dosing ranges. For fluoxetine, the higher end of the dosing range, 60 mg/day, can be necessary for response.[83] With other agents, most clinicians initially target the bottom to the middle of the dosing range and increase the dose if there is an inadequate response. Slow titration is needed to allow time to develop tolerance to adverse effects. If TCAs are used, serum concentration monitoring is recommended to ensure that absorption is not compromised by purging.

8 The time for antidepressant onset of effect in bulimia is unclear. In the absence of data, the definition of a therapeutic trial from the depression literature (4–8 weeks at a therapeutic dose) should be used. Because the majority of subjects will not experience a complete remission, and there are few data on predictors of response or whether switching to another class will improve response, a clear and specific target should be stated initially.[18]

9 Optimal duration of treatment after response is poorly defined, although most clinicians treat for 9 months to 1 year and then reevaluate.

CLINICAL CONTROVERSY

Antidepressant therapy is the preferred treatment intervention for bulimia nervosa, however it is unclear whether long-term pharmacologic treatment reduces the risk of relapse compared to shorter duration treatment interventions of a year or less.

The evidence is mixed as to whether any early benefit is sustained; hence, the decision to continue treatment should be made based on both initial response and the maintenance of that benefit. If the symptoms return within a few months after antidepressant discontinuation, then the treatment might need to be reinitiated.

Figure 73–2 describes criteria for medication use in bulimia, but it must be noted that no evidence-based consensus for treatment has been endorsed, even with the recent guidelines, meta-analyses, and reviews of the literature.[4,18,24,55,57,59,66]

Mood Stabilizers (Lithium and Anticonvulsants) Because of the lack of evidence demonstrating their benefit, lithium and anticonvulsants are reserved for bulimic patients with a comorbid bipolar affective disorder.[18,84] Target serum concentrations and doses are similar to those used for patients with seizure or mood disorders. Lithium must be used cautiously, as fluid shifts related to purging and laxative abuse increase the risk of toxicity. The adverse effect of weight gain often makes mood stabilizers and anticonvulsants unacceptable to patients in the long term.

Miscellaneous Agents Low-dose benzodiazepines before meals can help reduce anxiety associated with refeeding, although long-term use is not warranted because of the risk of abuse and dependence. One double-blind trial with ondansetron has shown benefit, but there are insufficient data to recommend a specific role for this agent.[85] Antipsychotics and appetite suppressants do not play a role in managing central symptoms of bulimia.[24]

Nonpharmacologic versus Pharmacologic Approaches

The combination of pharmacologic and nonpharmacologic measures appears to produce the best chance for a positive outcome for patients with bulimia nervosa.[55] Antidepressants, specifically SSRIs, are the class of choice in bulimic patients, whereas other medications are reserved for patients with comorbid psychiatric conditions. Only in unusual circumstances should patients be treated with antidepressants alone. Evidence suggests the greatest benefit is during the acute phase of treatment, whereas data are mixed supporting their role in the prevention of relapse.

BINGE EATING DISORDER

As in anorexia and bulimia, CBT and interpersonal psychotherapy seem to be the most effective interventions.[24] Antidepressants, anticonvulsants, and appetite suppressants are the pharmacologic agents with the greatest promise in BED, but data are limited, trials are short in duration (20 weeks or less), and whether there is sustained benefit is unclear.[86] Although reports are mixed, antidepressants have demonstrated efficacy as monotherapy at reducing binge eating and improving depressed mood during the acute phases of

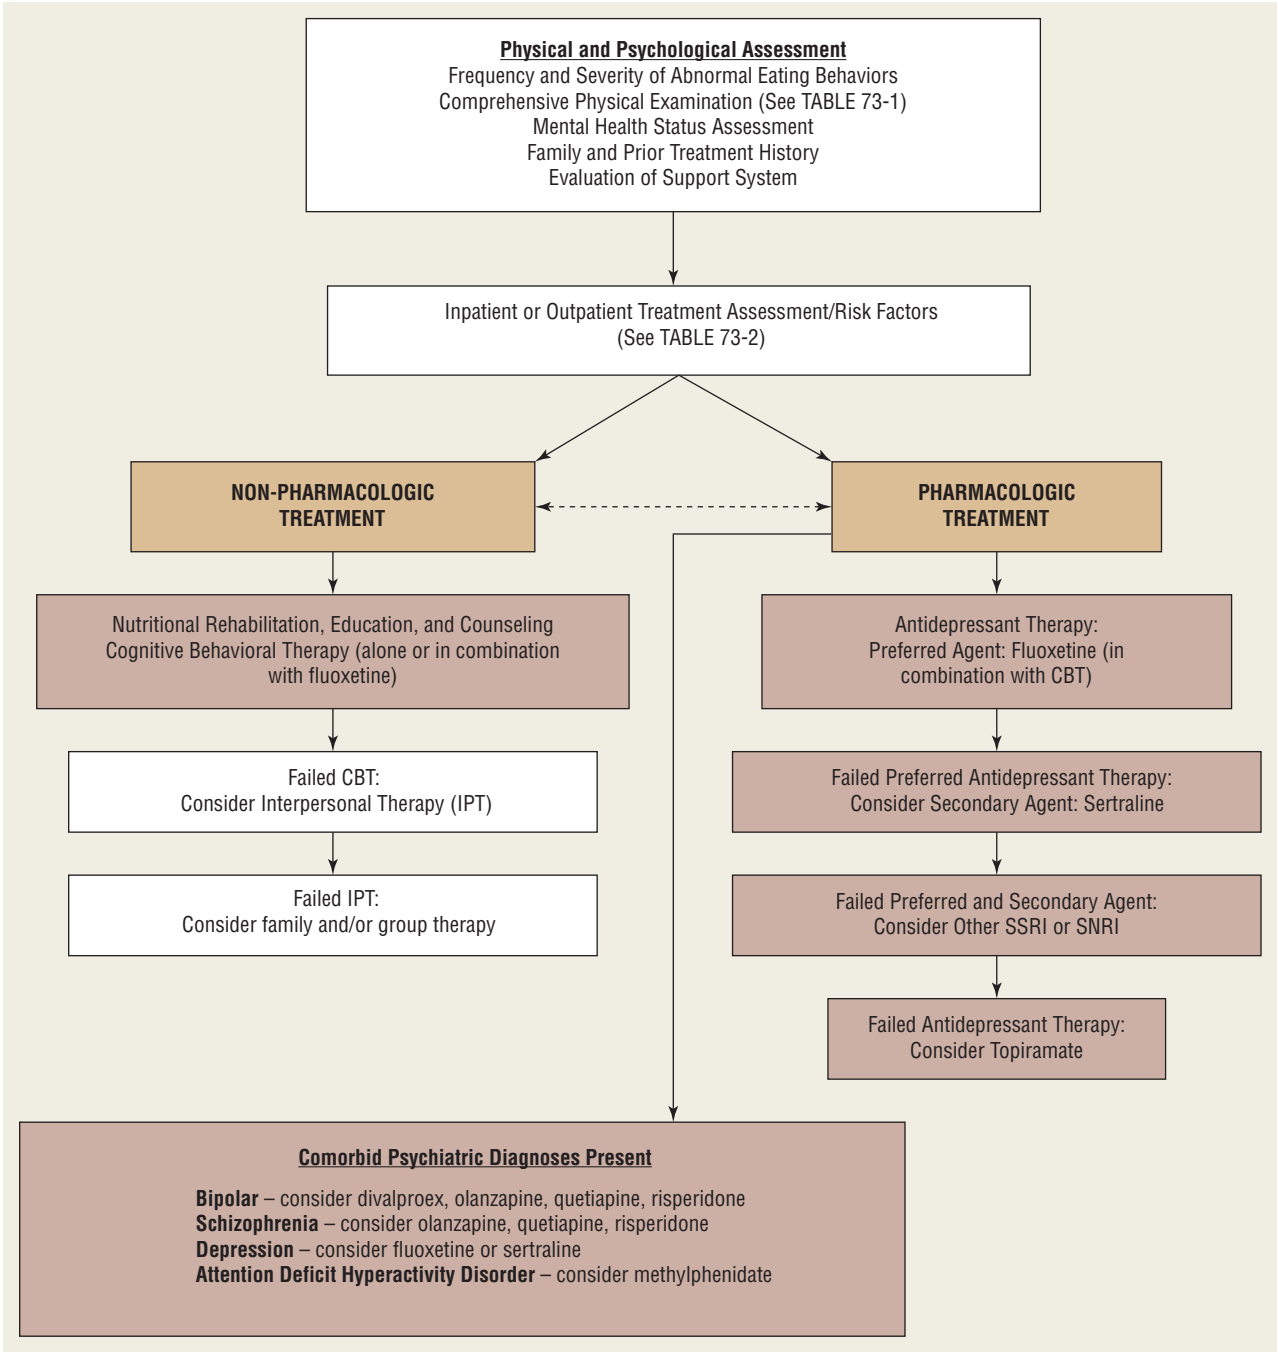

FIGURE 73-2. Bulimia nervosa treatment algorithm. (CBT, cognitive behavioral therapy; IPT, interpersonal pyschotherapy; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.)

the illness compared with placebo, but they can also be used in combination with CBT to augment response.[24,87–90] The majority of the data are with SSRIs given at antidepressant doses.[86] Topiramate 50 to 600 mg daily (a median dose 200 mg/day) has produced benefit in patients with impulse control disorder and because it promotes weight loss. Short-term data demonstrating superiority over placebo have been published, but data beyond 12 weeks' duration are lacking.[91] Sibutramine 10 to 15 mg/day has also demonstrated benefit in reducing weight and binge frequency in obese BED patients compared with placebo.[92] Orlistat 120 mg given three times daily, along with a calorie-restricted diet, has produced weight reduction in obese patients with BED.[93] Zonisamide (100–600 mg/day) has also displayed benefit at reducing binge eating frequency and promoting weight loss.[94]

In summary, the question of where BED fits on the diagnostic spectrum continues to be explored. Current literature suggests that three different types of pharmacologic agents (SSRIs, topiramate, and sibutramine) hold promise in the short term, but long-term data are lacking. As with other eating disorders, nonpharmacologic treatments are the key to a successful outcome.

PHARMACOECONOMIC CONSIDERATIONS

There are no formal evaluations of the economic impact of eating disorders on individual patients, on global healthcare costs, or on indirect costs such as unemployment, premature death, or disability payments. The chronic course, severe disability, and lack of

improvement in up to one-third of patients suggest a significant cost impact. Clinicians should contribute to the appropriate use of resources by ensuring that medications are used in situations in which there is evidence demonstrating their benefit and that they are never used as the sole treatment modality. For example, antidepressants are started after normal weight is restored in anorexic patients and not to treat depressive symptoms in significantly malnourished patients. One study evaluating the relative costs of CBT alone, medication alone, or combination treatment in bulimia concluded that if overall effectiveness was the prime consideration, then CBT, with medication added if the response was inadequate, was the best approach. If cost-effectiveness was the basis for making treatment decisions, then antidepressants alone as a first step, followed by the addition of CBT when response is inadequate, is the preferred next intervention.[92]

EVALUATION OF THERAPEUTIC OUTCOMES

ANOREXIA NERVOSA

A combination of subjective and objective measures is used to assess patient response. A reduction in the frequency and severity of abnormal eating habits, normalized exercise patterns and laboratory tests, and a sustained weight close to age-matched normals are key indicators of response. A diary recording exercise frequency, menses, food intake, patterns of eating, and associated feelings while eating is a useful tool to track progress, especially in the outpatient setting. Weekly weigh-ins on the same scale, preferably at a clinician's office, help monitor progress early in treatment and reduce the focus on weight and anxiety caused by the variability found among different scales. Follow-up laboratory tests and ECGs are not part of routine monitoring unless the patient is restricting food intake, is purging, or continues to lose weight despite treatment. Inpatients require daily assessment of weight and caloric intake, vital signs, and urine output because of the more severe nature of their illness. They also can need monitoring of bathroom privileges early in their care. A healthy weight gain of no more than 0.2 to 0.5 kg (0.4 to 1.1 lb) per week toward a goal of 90% to 95% of normal weight or a BMI greater than 18.5 kg/m^2 is a critical sign of treatment success. A patient's use of coping skills and contingencies for dealing with stress other than manipulating food consumption also should be assessed. Antidepressants can assist in alleviation of persistent depression, anxiety, and obsessions, after weight restoration. Improvement in mood is expected to occur within 8 weeks. Patients receiving TCAs should be evaluated for dry mouth, constipation, hypotension, and sedation. Patients receiving SSRIs should be monitored for agitation, drug-induced anorexia, nausea, weight loss, and insomnia. The decision to use long-term medication must be based on specific and sustained improvement in the target symptoms, balanced against adverse effects.

BULIMIA NERVOSA

An individualized treatment and monitoring plan begins with a thorough assessment describing the baseline frequency and severity of treatment-responsive target symptoms and other associated findings. The assessment must be comprehensive, as a patient can hide his or her illness by shifting from one type of behavior to another (e.g., exercise to purging).

A comprehensive assessment includes a description of psychiatric symptoms, physical findings, frequency and severity of binge–purge episodes, laxative and ipecac use, exercise patterns, and laboratory and ECG abnormalities. Interpersonal and relationship problems should also be evaluated. Some findings indicating a more chronic course of illness, such as salivary gland inflammation and erosion of dental enamel, can take months to reverse or might never normalize. Hence, these are not sensitive indicators of early treatment response. Data describing a patient's baseline level of functioning and previous response to treatment should be used to set goals in the current treatment plan.

Antidepressant response usually occurs within 4 to 8 weeks after the onset of treatment. If response does not occur, binge–purge behavior should be considered as a factor potentially contributing to the malabsorption of medication. If this behavior is not present, then every attempt should be made to maximize the dose. Serum concentration monitoring, when appropriate as with TCAs, should be done periodically (every 3–6 months if a patient is responding and tolerating the medication, or more frequently if clinically indicated). Evaluation of previously described adverse effects also should be part of the monitoring plan. If the patient responds, he or she should be followed for 6 to 12 months, then reassessed for the need for ongoing medication. If the patient relapses on medication discontinuation, then the medication should be restarted.

Ambulatory eating disorder patients present a particular challenge to clinicians. Impulsivity associated with bulimia nervosa can increase the risk for suicide. Prescriptions should be limited to small supplies. In addition, pharmacists should be alert to persons who make large or frequent purchases of laxatives or ipecac syrup, as this is an indicator of possible bulimic behaviors.

CONCLUSION

Our understanding of the pathophysiology and symptomatology of eating disorders has improved significantly over the past several years. Medication serves an adjunctive role to a variety of psychosocial therapies in anorexia nervosa, whereas it plays a more central role in bulimia nervosa and BED treatment. By gaining a greater understanding of the underlying physiologic changes and the psychosocial complications associated with eating disorders, treatment plans can be specifically designed for an individual patient with the goal of improving his or her quality of life.

ACKNOWLEDGMENTS

The author acknowledges the contributions of Patricia A. Marken, PharmD, and Roger W. Sommi, PharmD, authors of the Eating Disorders chapter (Chapter 66) in the seventh edition of *Pharmacotherapy: A Pathophysiologic Approach.*

ABBREVIATIONS

BDNF: Brain-derived neurotrophic factor

CHAPTER 74

Substance-Related Disorders: Overview and Depressants, Stimulants, and Hallucinogens

PAUL L. DOERING

KEY CONCEPTS

1. Problems related to abuse of chemical substances can occur acutely (e.g., respiratory arrest from using heroin) or after some length of time (e.g., dependence or withdrawal from continued use of an opiate).
2. Pharmacotherapy of substance-related disorders is most often adjunctive to other modes of therapy such as counseling and intense psychotherapy.
3. Withdrawal from certain classes of drugs (e.g., benzodiazepines or barbiturates) can be life-threatening, and steps must be taken to ensure that withdrawal is gradual and that it takes place in closely supervised settings.
4. While there is much research focusing on drugs to treat the underlying addictive processes, to date the successes have been few. Prevention is the key. Because of their knowledge of pharmacology and the actions of drugs on the body, health professionals can play a key role in education of young people on the dangers of recreational drug use.

In 2001, the Schneider Institutes for Health Policy at Brandeis University[1] boldly declared that the abuse of alcohol, tobacco, and other drugs (ATOD) was the nation's number one health problem. Sadly, not much has changed since then to change their assessment. There are more deaths, illnesses, and disabilities from substance abuse than from any other preventable health condition. A recent report from the National Center on Addiction and Substance Abuse at Columbia University[2] found that for the year 2005 federal, state, and local government spending as a result of substance abuse and addiction was at least $467.7 billion.[2] A heavy smoker will stay 25% longer when hospitalized than a nonsmoker, and a problem drinker will stay four times as long as a nondrinker.[1] Of the more than 2 million deaths each year in the United States, approximately one in four is attributable to alcohol, illicit drug, or tobacco use.

In addition, one half to two thirds of homicides and serious crimes involve alcohol. Nearly one half of men arrested for homicide and assault test positive for an illegal drug.[1,2] ATOD abuse contributes to family problems, with one in four Americans reporting that alcohol has been a cause of trouble in the family, and alcohol abuse plays a part in one of three failed marriages.[1,2]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Since publication of the last edition of this textbook, a disturbing trend in drug abuse has continued: the use of medicinal drugs for nonmedicinal purposes. Between 1995 and 2002 there was a 163% increase in the number of emergency room visits tied to the abuse of prescription drugs, and these percentages continue to increase.[3] Prescription drugs now are a factor in one fourth of all overdose deaths reported in the United States. Central nervous system (CNS) agents, primarily analgesics (pain relievers), were involved in slightly less than one half (47%) of all drug-related suicide attempts that presented to emergency departments in 2005, including both prescription and over-the-counter (OTC) formulations. More than 56% of suicide-related emergency department visits included psychotherapeutic agents (e.g., benzodiazepines or antidepressants).[3]

This chapter and the next focus on the problems associated with the abuse of chemical substances and what clinicians can do to help deal with these problems.

KEY DEFINITIONS

The lack of a common vocabulary in substance abuse treatment and prevention leads to several problems. Wide arrays of terms are in common use, many without precise meaning. This lack of universal agreement on language hampers effective communication among professionals and leads to difficulties in formulating public policy and administering third-party reimbursement programs. The Liaison Committee on Pain and Addiction, a collaborative effort of the American Academy of Pain Medicine, the American Pain Society, and the American Society of Addiction Medicine has developed definitions related to the use of medications for the treatment of pain consistent with current understanding of relevant neurobiology, pharmacology, and appropriate clinical practice. The definitions have been approved by each of the three collaborating organizations. The following definitions resulted from this consensus development committee.[4]

- *Addiction* is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following 5Cs: **c**hronicity, impaired **c**ontrol over drug use, **c**ompulsive use, **c**ontinued use despite harm, and **c**raving.
- *Drug abuse* is a maladaptive pattern of substance use characterized by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use creating physical danger, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.

- *Physical dependence* is a state of adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.
- *Tolerance* is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time.

EPIDEMIOLOGY

NATIONAL SURVEY ON DRUG USE AND HEALTH

The National Survey on Drug Use and Health (NSDUH)[5] is the primary source of statistical information on the use of illegal drugs by the U.S. population. Conducted by the federal government since 1971, the survey collects data from a representative sample of the population at their place of residence.

In 2008, the survey found that an estimated 20.1 million Americans aged 12 or older were current illicit drug users, meaning they had used an illicit drug during the month prior to the survey interview. An estimated 22.2 million Americans suffered from substance dependence or abuse because of drugs, alcohol, or both. The 2008 survey found that marijuana was the most commonly used illicit drug (15.2 million past month users). About 6.2 million Americans—2.5% of the population—said they abused prescription drugs in the past month in 2008, a decrease from 2.8% of the population in 2007, but still a monumental problem in our country.[5]

MONITORING THE FUTURE STUDY

Every year the Institute for Social Research at the University of Michigan conducts its Monitoring the Future Study, supported under a series of research grants from the National Institute on Drug Abuse.[6] A main purpose of this research is to study changes in the beliefs, attitudes, and behavior of young people in the United States.[6]

In 2009, 46,097 U.S. students in 8th, 10th, and 12th grades in 389 public and private secondary schools were surveyed.[6] Findings show that smoking marijuana is gaining popularity among U.S. teens, even though they have cut down on smoking cigarettes, binge drinking, and using methamphetamine.[6] Researchers postulate that the increase of smoking marijuana is partly attributable to the national debate over medical use of cannabis which may make the drugs seem safer to teenagers. In addition to marijuana, fewer teens also view prescription drugs and Ecstasy as dangerous, which may explain why more teens also are abusing prescription pain pills and attention-deficit drugs.[6]

Illicit or street drug use has shown considerable declines over the past decade or so, perhaps indicating a shift toward abuse of other prescription drugs. These include sedatives, tranquilizers, and narcotic drugs other than heroin (most of which are analgesics). As a result, they have become a much more important part of the nation's drug abuse problem.[6]

SUBSTANCE ABUSE EMERGENCIES: THE DAWN PROGRAM

Since the early 1970s, the Drug Abuse Warning Network (DAWN),[3] an ongoing national survey of hospital emergency departments (EDs), has collected information on patients seeking hospital emergency department treatment related to their use of an illegal drug or the nonmedical use of a legal drug. These data allow healthcare professionals to be better prepared to react to medical emergencies arising from illegal drug use and to target prevention and education programs to specific drug-using groups or populations. Unfortunately, there is about a 2-year lag in the occurrences of ED visits and publication of the data and a limited number of metropolitan areas is surveyed.[3]

DAWN defines a *drug-related episode* as an ED visit that was induced by or related to the use of an illegal drug(s) or the nonmedical use of a legal drug for patients aged 6 to 97 years. In 2006, hospitals in the United States delivered a total of 113 million ED visits, and DAWN estimates that 1,742,887 ED visits were associated with drug misuse or abuse. Of those ED visits, some key findings include the following:

- 31% involved illicit drugs only
- 28% involved pharmaceuticals only
- 7% involved alcohol only in patients under the age of 21
- 13% involved illicit drugs with alcohol
- 10% involved alcohol with pharmaceuticals
- 8% involved illicit drugs with pharmaceuticals
- 3% involved illicit drugs with pharmaceuticals and alcohol

ECONOMIC IMPACT OF SUBSTANCE ABUSE

Substance abuse and addiction have an enormous impact on the economy. Over the years, the National Center on Addiction and Substance Abuse (CASA) at Columbia University has conducted studies aimed at quantifying the costs to local, state, and federal governments and agencies. The most recent figures[2] are based on 2005 spending because that was the most recent year for which data were available over the course of the latest study.

As noted earlier, substance abuse and addiction cost federal, state, and local governments at least $467.7 billion in 2005. The CASA report found that of $373.9 billion in federal and state spending, 95.6% ($357.4 billion) went to "shovel up the consequences and human wreckage of substance abuse and addiction";[2] only 1.9% went to prevention and treatment, 0.4% to research, 1.4% to taxation and regulation, and 0.7% to interdiction.

Of the $3.3 trillion total federal and state government spending, $373.9 billion—11.2%, more than $1 of every $10—was spent on tobacco, alcohol, illegal, and prescription drug abuse, addiction, and its consequences.[2]

For every $100 spent by state governments on substance abuse and addiction, the average spent on prevention, treatment, and research was $2.38. For each dollar in alcohol and tobacco taxes and liquor store revenues that federal and state governments collect, they spend $8.95 dealing with the consequences of substance abuse and addiction.[2]

ACUTE VERSUS CHRONIC PROBLEMS

1 Misuse of chemical substances causes problems of two types: those that occur acutely and those that arise after continued use of a drug. Acute problems are usually predictable, given the pharmacology of the drug. Chronic abuse of chemical substances can cause a wide array of physical, psychological, and psychiatric morbities. The substance-induced disorders discussed here mainly include intoxication and withdrawal.

1 The essential feature of substance dependence is the continued use of the substance despite adverse substance-related problems. The criteria for substance dependence are the same for each of the drugs or drug classes, varying only to fit the unique pharmacologic properties of each drug. Patients who take prescribed drugs for appropriate medical indications and in correct doses may still show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than being tapered. Tolerance and physical dependence are

inevitable consequences of chronic treatment with opioids and certain other drugs, but by themselves, tolerance and physical dependence do not imply "addiction." To meet *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (*DSM-IV-TR*) criteria[7] for the diagnosis of substance dependence, at least three of the following must be present at any time in a 12-month period:

1. Tolerance
2. Withdrawal, indicated by the appearance of the characteristic withdrawal syndrome or the use of the same or related drug to relieve or avoid withdrawal symptoms
3. Substance is taken in larger amounts or over a longer period of time than was intended
4. Patient has a persistent desire or unsuccessful efforts to cut down or control substance use
5. Considerable time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects
6. Social, occupational, or recreational activities are given up or reduced because of substance use
7. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychologic problem caused or exacerbated by the substance

In 2008, an estimated 22.2 million persons (8.9% of the population aged 12 or older) were classified with substance dependence or abuse in the past year based on these criteria. Of these, 3.1 million were classified with dependence on or abuse of both alcohol and illicit drugs, 3.9 million were dependent on or abused illicit drugs but not alcohol, and 15.2 million were dependent on or abused alcohol but not illicit drugs.[5]

The characteristic feature of *substance abuse* is a maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance.[7] Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.[7] *Intoxication* refers to the development of a substance-specific syndrome after recent ingestion and presence in the body of a substance, and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the CNS. Examples include belligerence, mood lability, impaired judgment, and impaired social or occupational functioning. Evidence for recent intake of the substance can be obtained from the history, physical examination, or laboratory examination. The most common changes involve disturbances in perception, wakefulness, attention, thinking, judgment, motor behavior, and interpersonal behavior.

As with most illnesses, the course and prognosis of the disorders of substance use and dependence are variable. Untreated physical withdrawal from CNS depressants is potentially life-threatening, but withdrawal almost always can be managed successfully with proper medical care. Getting patients who are drug dependent to stop using drugs is very difficult, and many patients return to drug use even after treatment. As many as 75% of treated, substance-dependent patients will relapse at least once. Many patients, however, are able to obtain recovery with treatment and continued care in 12-step programs such as Alcoholics Anonymous or Narcotics Anonymous. Substance dependence or addiction can be viewed as a chronic illness that can be controlled successfully with treatment but cannot be cured and is associated with a high relapse rate. Without treatment, the course can progress to life-threatening severity, resulting from the effects of the drug, drug contaminants, or medical complications of use.[7] Recently, the definitions used in the *DSM-IV-TR* criteria have been criticized.[8] Although an in-depth discussion of the mechanism of drug addiction is beyond the scope of this chapter, the interested reader is directed to a review article that presents the current understanding of the biology of drug addiction.[9]

DIVERSION OF PHARMACEUTICAL CONTROLLED SUBSTANCES

The nonmedical or recreational use of pharmaceutical controlled substances has dramatically increased in the United States in recent years, although there has been a slight downward trend when comparing 2007 to 2008. About 6.2 million Americans—2.5% of the population—said they abused prescription drugs in the past month in 2008. An estimated 4.7 million persons used pain relievers nonmedically in the past month in 2008, 1.8 million used tranquilizers, 904,000 used stimulants, and 234,000 used sedatives.[5]

In 2008 4.7 million teens reported they had abused a prescription drug at some time in their lives.[10,11] Family medicine cabinets were cited as the main source for obtaining prescription drugs. About 4 out of 10 (41%) teens agree that prescription drugs are much safer to use than illegal drugs. Furthermore, the same study concluded that 31% believe there is "nothing wrong" with using prescription medicines without a prescription "once in awhile."[10,11] From a supply standpoint for the first time, this year researchers asked 12- to 17-year olds how fast they can get prescription drugs, and found that 19% of teens (4.7 million) can get prescription drugs (in order to get high) in an hour; 35% (8.7 million) can get prescription drugs within a day.[11]

One of the main factors contributing to the nationwide increase in the diversion of pharmaceutical controlled substances has been the rise in the number of Internet sites that sell or facilitate the sale of these drugs for other than legitimate medical purposes.[12,13] So-called "prescription mills" remain a major source of diversion. The advent of rogue websites that cater to those who abuse pharmaceutical controlled substances has allowed the criminal operators of these sites to exploit the anonymity of the Internet to generate illicit sales of controlled substances, including prescriptions to an extent far exceeding those of any in-person prescription mill.[13] This is particularly evident when examining the data relating to the sales of hydrocodone, which is the most widely abused pharmaceutical controlled substance in the United States. According to data provided to the U.S. Drug Enforcement Administration (DEA)[13] in 2006 by registered distributors of controlled substances, 34 U.S. pharmacies supplying rogue Internet sites dispensed more than 98 million dosage units of hydrocodone. Hence, these pharmacies each dispensed an average of approximately 2.9 million dosage units of hydrocodone per pharmacy in a single year. By means of comparison, the average pharmacy in the United States dispenses approximately 88,000 dosage units of hydrocodone per year.[13]

For 5 years, CASA at Columbia University has been tracking the availability of controlled prescription drugs over the Internet. In an in-depth white paper on the subject of Internet diversion of prescription drugs, CASA referred to the Internet as a "Pharmaceutical Candy Store."[12] The disheartening results of this study helped Congress passed the Ryan Haight Act,[13] federal legislation that, effective April 13, 2009, made it illegal under federal law to "deliver, distribute, or dispense a controlled substance by means of the Internet, except as authorized by [the Controlled Substances Act]."

CNS DEPRESSANTS

BENZODIAZEPINES AND OTHER SEDATIVE-HYPNOTICS

Emergency department visits involving benzodiazepines clearly outnumber those involving any of the other types of

psychotherapeutic agents. DAWN estimates that 195,625 ED visits associated with nonmedical use of pharmaceuticals involved benzodiazepines in 2006.[3] Alprazolam and clonazepam are the most frequent benzodiazepines seen in emergency department visits (65,236 visits and 33,557 visits, respectively). ED visits by patients taking diazepam and lorazepam were fewer (19,936 and 23,720, respectively).[3]

In clinical practice, the benzodiazepines largely have replaced the short-acting barbiturates and other nonbarbiturate sedative-hypnotics. Benzodiazepines with faster onset (e.g., diazepam) tend to be preferred by the recreational drug user because they are reinforcing. Flunitrazepam emerged in the mid-1990s as an illegal drug in the United States that was predominantly abused recreationally and associated with sexual assaults.[14]

PRESENTATION OF BENZODIAZEPINE INTOXICATION AND WITHDRAWAL

General

- The intoxicated patient may be in acute distress in overdoses or when benzodiazapines are combined with alcohol.
- Patients in withdrawal may also be in acute distress and should be treated with a benzodiazepine taper to prevent seizures.

Symptoms

- The patient may experience memory impairment, drowsiness, visual disturbances, confusion, and gastrointestinal disturbances. Patients may appear intoxicated, with slurred speech, poor coordination, swaying, and bloodshot eyes, with or without the odor of alcohol.[11–14]

Signs

- Hypotension or nystagmus may be observed, and urinary retenion may occur.

Laboratory Tests

- Qualitative testing to confirm presence of benzodiazepines is useful for diagnostic purposes, but quantitative plasma concentrations are usually not clinically useful.

A dramatic drop in cases of flunitrazepam abuse followed the legal reclassification of the drug as a schedule I substance in Florida (and other states) in February 1997. The recent rise in alprazolam and clonazepam abuse/misuse coincides with the decreased use of flunitrazepam and represents a new trend in abuse of the benzodiazepines. Alprazolam (Xanax) has become particularly popular and is known on the street by its slang names, "Z-Bars," "Zandy bars," "footballs," and "Zannies," among others. Young people often take alprazolam or other benzodiazepines before going to the bar or dance club, ostensibly to lower the amount of alcoholic beverage needed to attain the desired level of intoxication. Unfortunately, this "pre-partying" is especially popular among women who do not like the taste of beer or find the caloric burden of drinking to be limiting. Sadly, whether taking intentionally or being given the drug without their knowledge or consent, these women become targets for sexual predators who know that the victim will have diminished recall of the events that take place. When a victim is unable to give precise details of what happened and when it happened, and is unable to identify the perpetrator, the chances of successful prosecution are greatly diminished.[14]

Because all benzodiazepines have abuse and dependence liability, patients cannot be switched from one benzodiazepine to another in hopes of decreasing a pattern of drug abuse or dependence behavior. Zolpidem, a nonbenzodiazepine, nonbarbiturate sedative, has been suggested to have little liability for physical dependence, but tolerance and withdrawal have been reported in association with its use as well.[15] Recent reports in the lay press have linked use of zolpidem to sleep walking, erratic driving, binge eating, and other similarly bizarre activities.

Benzodiazepines generally do not cause life-threatening respiratory depression (unless taken with other sedatives), as do the barbiturate-like drugs.[16] Long-term use of even therapeutic doses of benzodiazepines can cause physical dependence and withdrawal symptoms after abrupt discontinuation.[16] Occurrence of hallucinations or seizures would indicate severe physical withdrawal.

2 Gradual tapering of dosage is also associated with less withdrawal and rebound anxiety than abrupt discontinuation. Dependence on sedative-hypnotics and benzodiazepines is summarized in Table 74–1. For additional information on benzodiazepine withdrawal, refer to Chapter 79.

TABLE 74-1 Dependence on Sedative-Hypnotics

Generic Name	Common Trade Names	Oral Sedating Dose (mg)	Physical Dependence Daily Dose and Time Needed to Produce Dependence	Time Before Onset of Withdrawal (hours)	Peak Withdrawal Symptoms (days)[a]
Benzodiazepines					
Alprazolam	Xanax	0.25–8	8–16 mg × 42 days (est.)	8–24	2–3
Clorazepate	Tranxene	7.5–15	45–180 mg × 42–120 days (est.)	12–24	5–8
Diazepam	Valium	5–10	40–100 mg × 42–120 days	12–24	5–8
Flunitrazepam	Rohypnol	1–2	8–10 mg × 42 days (est.)	24–36	2–3
Barbiturates					
Amobarbital	Amytal	65–100	Same	8–12	2–5
Secobarbital	Seconal, Seco-8	100	800–2,200 mg × 35–37 days	6–12	2–3
Equal parts of secobarbitaland amobarbital	Tuinal	100	Same	6–12	2–3
Pentobarbital	Nembutal	100	Same	6–12	2–3
Nonbarbiturate sedative-hypnotics					
Chloral hydrate	Noctec	250	Exact dose unknown; 12 g/day chronically has led to delirium upon sudden withdrawal	6–12	2–3
Meprobamate	Equanil, Miltown, Meprotabs	400	1.6–3.2 g × 270 days	8–12	3–8

[a]Withdrawal symptoms are tremor, tachycardia, diaphoresis, nausea, vomiting, elevated blood pressure, delirium, seizures, and hallucinations.

γ-HYDROXYBUTYRATE

γ-Hydroxybutyrate (GHB) is a chemical compound structurally similar to the inhibitory brain neurotransmitter γ-aminobutyric acid. Primary groups using GHB include party and nightclub attendees. Like flunitrazepam, GHB is also characterized as a date rape drug.[14] Manifestations of acute GHB toxicity include coma, seizures, respiratory depression, and vomiting. Other documented effects of GHB include amnesia and hypotonia, abnormal sequence of rapid eye movement (REM) and non-REM sleep, and anesthesia. Doses greater than 50 mg/kg can decrease cardiac output and produce severe respiratory depression, seizure-like activity, and coma; coma and respiratory depression can be potentiated by concomitant use of alcohol. Treatment is restricted to nonspecific supportive care. Figure 74–1 shows a protocol recommended for treating suspected GHB overdose.

Until fairly recently, the majority of GHB sold on the streets was manufactured using inexpensive kits obtained over the Internet. The decreased Internet availability of kits to make GHB has been accompanied by an increased availability of chemical precursors to GHB as well as GHB analogs. Available in gyms and health food stores, these substances include γ-butyrolactone (GBL) and 1,4-butanediol.[17] GBL is converted in the body to GHB. Labels of marketed products can use unfamiliar synonyms to disguise the actual content. GBL is also known by the names 2(3H)-furanone dihydro, butyrolactone, 4-butyrolactone, dihydro-2(3H)-furanone, 4-butanolide, 2(3H)-furanone, dihydro, tetrahydro-2-furanone, and butyrolactone-γ.

GHB is being used and is being studied for a number of legitimate medical uses, including its use as an anesthetic, treatment of narcolepsy, and treatment of drug addiction. In fact, a pharmaceutical version of GHB (called by the alternate name of sodium oxybate [Xyrem]) was approved by the U.S. Food and Drug Administration (FDA) for cataplexy attacks in patients with narcolepsy in 2002. In November 2005, the FDA approved sodium oxybate for the treatment of excessive daytime sleepiness in patients with narcolepsy. Deaths from the pharmaceutical dosage forms have been reported.[18]

CARISOPRODOL

Carisoprodol is a prescription drug marketed since 1959 and used in primary care settings for the treatment of musculoskeletal conditions associated with muscle spasms and back pain. Its effectiveness for this use has been questioned.[19] It is marketed in the United States as Soma and in the U.K. as Carisoma as well as many generic versions. It is both structurally and pharmacologically related to meprobamate, a schedule IV substance. In fact, a substantial percentage of the drug is metabolized to meprobamate,[19] a drug with substantial barbiturate-like properties.

In legitimate medical practice carisoprodol is used as an adjunct to rest, physical therapy and other measures for relief of acute, painful musculoskeletal conditions.[19] The standard dosage for adults is 350 mg 3 times daily and at bedtime. Approximately 10.58 million prescriptions for carisoprodol were dispensed in 2008.

Skeletal muscle relaxant effects of carisoprodol may be related to its sedative properties.[19,20] Adverse effects are mostly related to

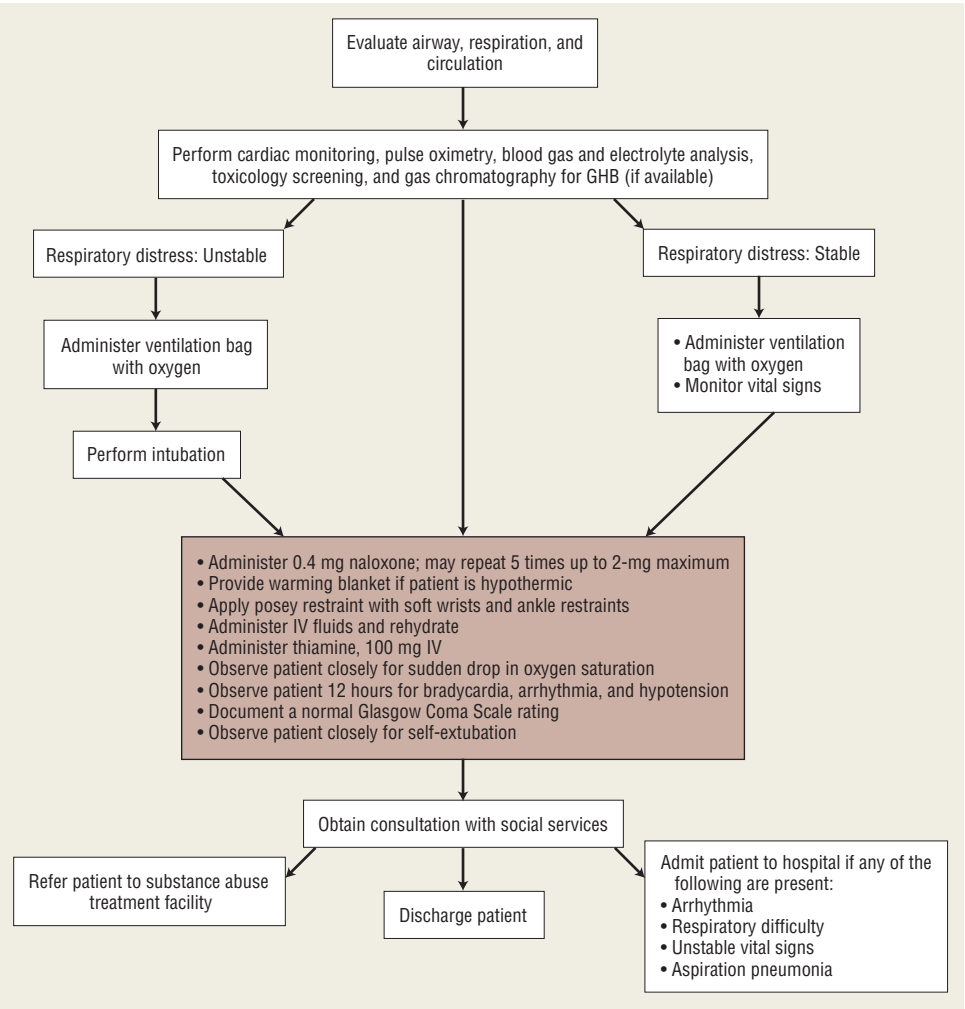

FIGURE 74-1. Protocol for treatment of suspected GHB (γ-hydroxybutyrate) overdose.

the CNS: drowsiness, dizziness, vertigo, ataxia, tremor, agitation, irritability, headache, depressive reactions, syncope, and insomnia. Carisoprodol may also adversely affect cardiovascular (tachycardia, postural hypotension, and facial flushing), gastrointestinal (nausea, vomiting, hiccup, and epigastric distress), and hematologic systems. It may cause idiosyncratic symptoms including extreme weakness, transient quadriplegia, ataxia, difficulty in speech, temporary loss of vision, double vision, dilated pupils, agitation, euphoria, confusion, and disorientation. Carisoprodol overdose has resulted in stupor, coma, shock, respiratory depression, and death.[20–22]

Data are clear that the diversion and abuse of carisoprodol have increased in the last decade.[18] According to 2007 NSDUH data, nonmedical use of carisoprodol by the U.S. population aged 12 and older was 1.1%, similar to or greater than the prevelance of abuse of other commonly abused schedule IV controlled drugs such as clonazepam (1.5%) and chlordiazepoxide (0.3%).[5] With prolonged abuse at high dosage, carisoprodol can lead to tolerance, dependence, and withdrawal symptoms in humans.[20]

According to the Diversion Drug Trends, published by the DEA on the trends in the diversion of controlled and noncontrolled pharmaceuticals,[19] carisoprodol continues to be one of the most commonly diverted drugs. Diversion and abuse of carisoprodol is prevalent throughout the country.

Ironically, carisoprodol is not controlled under the federal Controlled Substances Act of 1970. It is currently scheduled under state law in Alabama, Arizona, Arkansas, Florida, Georgia, Hawaii, Indiana, Kentucky, Louisiana, Massachusetts, Minnesota, Nevada, New Mexico, Oklahoma, Oregon, Texas, and West Virginia.

OPIATES

The National Household Survey on Drug Abuse indicated that an estimated 3,091,000 U.S. residents aged 12 and older have used heroin at least once in their lifetime. Collectively, use of opiates other than heroin is far more common. Of the 12 years of age and older population, an estimated 4.7 million people used narcotic pain relievers nonmedically, and 3.1 million persons used what Substance Abuse and Mental Health Services Administration classified as "OxyContin" nonmedically at least once in their lifetime.[23]

PRESENTATION OF OPIOID INTOXICATION AND WITHDRAWAL

General

- Onset of the acute phase of withdrawal ranges from a few hours after stopping heroin to 3 to 5 days after stopping methadone. The duration of withdrawal ranges from 3 to 14 days.
- Opioid withdrawal is not fatal unless there is a concurrent medical problem of major concern.
- The presence of delirium should raise the question of concurrent withdrawal from another drug, such as alcohol, or another cause of delirium possibly secondary to drug use.

Symptoms

- During withdrawal, patients can experience piloerection, insomnia, muscle aches, and yawning. While intoxicated, patients can experience euphoria, dysphoria, apathy, sedation, or attention impairment.

Signs

- Fever, lacrimation, diaphoresis, or diarrhea may be observed during withdrawal. Motor retardation, slurred speech, and miosis may be observed during intoxication.

Laboratory Tests

- Treatment is based more on clinical presentation because plasma opioid levels may not be clinically useful.

Other Diagnostic Tests

- Arterial blood gases, pulse oximetry, and pulmonary function tests are useful to assess respiratory depression.

By crushing controlled-release tablets, drug abusers can get the full 12-hour or more of narcotic effect almost immediately. Snorting or injecting the crushed tablet can lead to overdose and death. Abuse of this drug has caused a nationwide discussion on whether drugs of this nature should be more closely regulated. Various position statements and points of view on the benefits and risks have been expressed, but the limited space here precludes an exhaustive review of the issues. An excellent review of the appropriate use of opioid therapy for chronic pain has recently been published, and the interested reader is directed there for more information.[24]

CLINICAL CONTROVERSY

There is considerable debate about the appropriate use of prescribed opiates and how this might contribute to the overuse or abuse of these same drugs for nonmedicinal purposes. Not all decisions that physicians and other prescribers make are going to be correct. Likewise, pharmacists are going to make the wrong decision by either declining to fill a prescription that is proper and appropriate or by filling one that is bogus. In the final analysis, mistakes in judgment are going to be made in both directions. Given this fact, in which direction should the health professional err? Should health practitioners give the patient the benefit of the doubt, writing or filling the prescription, even if their decision ultimately turns out to be wrong? Or should the mandate be in the other direction: refuse to prescribe pain medicines or refuse to fill the prescriptions, even when, in truth, the prescription is appropriate and valid? Most healthcare professional assume that complaints of pain are real and prescribe accordingly.

METHADONE

The use of methadone has increased sharply, partially in response to the increased scrutiny given oxycodone products in the past few years. Methadone prescriptions for pain management grew from about 531,000 in 1998 to about 4.1 million in 2006, a nearly eightfold increase. The FDA approved methadone for treating pain in 1947, but from the early 1970s until the late 1990s, the drug was primarily used for treating addiction. In the mid-1990s, various national pain-related organizations began to issue guidelines for treating and managing pain, including using opioids to treat both cancer and noncancer pain. At first, methadone was prescribed more for the treatment of cancer pain, but it has been increasingly prescribed for the treatment of chronic noncancer pain. Methadone's advantages include that it costs less than other opioids used to treat pain, and it comes in multiple forms.[25]

Methadone has pharmacologic properties unique among opioids, and as a result, a lack of knowledge about methadone among practitioners and patients has been identified as a factor contributing to the increased number of deaths observed in recent years. DEA data suggest that the abuse of methadone diverted from its intended purpose has also contributed to the rise in overdose deaths, as the

number of methadone drug items seized by law enforcement and analyzed in forensic laboratories increased 262%, from 2,865 in 2001 to 10,361 in 2007.[25]

To improve safety, in 2006, the FDA issued a Public Health Advisory[26] that included new labeling information regarding the use of methadone for pain and modified dosage instructions for those beginning pain management treatment with methadone. Methadone's elimination half-life (8–59 hours) is longer than its duration of analgesic action (4–8 hours). Healthcare professionals were reminded that methadone's peak respiratory depressant effects typically occur later, and persist longer than its peak analgesic effects. The FDA advised that during treatment initiation, methadone's full analgesic effect is usually not attained until 3 to 5 days of dosing.

Cross-tolerance between methadone and other opioids is incomplete. This incomplete cross-tolerance makes the conversion of patients on other opioids to methadone complex and does not eliminate the possibility of methadone overdose, even in patients tolerant to other opioids. Deaths have been reported during conversion from chronic, high-dose treatment with other opioid agonists to methadone. It is critical to understand the pharmacokinetics of methadone when converting patients from other opioids to methadone. Particular vigilance is necessary during treatment initiation, during conversion from one opioid to another, and during dose adjustments. Also, there are pharmacokinetic and pharmacodynamic drug interactions between methadone and many other drugs. Thus drugs administered concomitantly with methadone should be evaluated for interaction potential.[26]

DEXTROMETHORPHAN

Dextromethorphan abuse is one of the most common (and most dangerous) examples of OTC drug abuse.[27] Intoxication from consuming large doses of cough syrup is known on the street as "robodosing" or "robotripping." Handsful of cough and cold remedies are sometimes called "skittles" because they look similar to the popular fruit candy. Dextromethorphan creates a depressant and mild hallucinogenic effect when taken in large doses. Since the drug is available over the counter, it is easily procured by adolescents. Those who use the cough syrup to get high are sometimes called "syrup heads."[27]

Excessive doses are needed to induce effects that include hyperexcitability, lethargy, ataxia, slurred speech, diaphoresis, hypertension, nystagmus, and mydriasis. When taken at much higher doses, it acts as a dissociative anesthetic, similar to phencyclidine (PCP, "angel dust") and ketamine ("Special K"). These are the effects sought by those who use the drug to get high. At these high doses, dextromethorphan also is a CNS depressant.[27,28]

The recommended treatment for acute overdoses of dextromethorphan is naloxone. Although reports of its efficacy are mixed, it may be helpful in reversing the CNS depressant and neurologic effects.[28]

Dextromethorphan powder is available through the Internet and by home laboratory extraction from pharmaceutical products. Five deaths in the United States have been attributed to dextromethorphan powder sold over the Internet.[27]

CNS STIMULANTS

COCAINE

Cocaine is perhaps the most behaviorally reinforcing of all drugs of abuse. Clinicians estimate that approximately 10% of people who begin to use the drug recreationally will go on to serious, heavy use. Once having tried cocaine, an individual cannot predict or control the extent to which he or she will continue to use the drug.

The most characteristic pharmacologic effect of cocaine is stimulation of the CNS. In the CNS, cocaine appears to mediate its effects primarily by blocking reuptake of catecholamine neurotransmitters such as norepinephrine and dopamine.

PRESENTATION OF COCAINE INTOXICATION AND WITHDRAWAL

General

- In overdoses, cocaine is a central nervous system and cardiac stimulant. Cocaine-elated deaths are often a result of cardiac arrest or seizures followed by respiratory arrest.

Symptoms

- Symptoms of intoxication include motor agitation, elation, euphoria, grandiosity, loquacity, hypervigilance, sweating or chills, nausea, and vomiting.
- Symptoms of withdrawal include fatigue, sleep disturbances, nightmares, depression, and changes in appetite.
- High doses of cocaine and/or prolonged use can trigger paranoia.

Signs

- Tachycardia, mydriasis, and either elevated or lowered blood pressure may be observed with overdose. Cardiac abnormalities (e.g., arrhythmias) and respiratory depression may be observed with overdose. Bradyarrhythmias, myocardial infarction, and tremors may be observed in acute withdrawal. Prolonged cocaine snorting can result in ulceration of the mucous membranes of the nose and can damage the nasal septum enough to cause it to collapse.

Laboratory Tests

- Qualitative drugs of abuse urine screening tests are useful, followed by confirmatory testing if necessary. Levels of the primary metabolite, benzoylecgonine, may help diagnose acute cocaine toxicity.

Other Diagnostic Tests

- Abnormal electroencephalograms may be observed with patients in acute withdrawal.

Cocaine is absorbed rapidly from virtually all sites of application. For many years, cocaine has been administered as the hydrochloride salt form, usually by inhalation, but also by injection. In the last 18 to 20 years, as the purity of cocaine hydrochloride obtained on the street declined, many users converted the cocaine hydrochloride to cocaine base, also known as "crack" or "rock." Smoking the drug leads to almost instant absorption and intense euphoria. Peak plasma concentrations of more than 900 ng/mL (3.0 μmol/L) have been achieved following inhalation of cocaine base vapors, compared with concentrations of only 150 to 200 ng/mL (0.49 to 0.66 μmol/L) achieved after inhalation of similar amounts of pure cocaine hydrochloride powder.[29]

The high from snorting can last 15 to 30 minutes, whereas that from smoking can last 5 to 10 minutes. Increased use can reduce the period of stimulation. An appreciable tolerance to the high can be developed, and many addicts report that they seek but fail to achieve as much pleasure as they did from their first exposure. Scientific evidence suggests that the powerful neuropsychologic reinforcing property of cocaine is responsible for an individual's continued use despite harmful physical and social consequences.

Recent research has helped clarify certain patterns of cocaine use, such as combining cocaine and alcohol. Such drug use would seem counterintuitive because cocaine is a CNS stimulant, and alcohol a CNS depressant. In the presence of alcohol, cocaine is metabolized to cocaethylene, a longer-acting but potent psychoactive compound compared to the parent drug.[30] The risk of death from cocaethylene is greater than from cocaine.[31] The cocaine-alcohol combination is one of the most commonly identified among individuals who come to hospital EDs with acute substance abuse problems.

Cocaine is metabolized and eliminated rapidly. The elimination half-life of cocaine is approximately 1 hour, and the duration of effect is very short.[29] The short duration of effect provides a powerful incentive for repeated use of the drug. Many users experience intense drug use cycling, sometimes lasting days, characterized by rapidly repeating doses of cocaine until their supply is exhausted. Laboratory monkeys, given a choice between food and cocaine around the clock for 8 days, consistently choose cocaine.

Complications of cocaine use frequently involve cardiovascular events.[32] Cocaine is a psychotomimetic drug, sometimes even at nontoxic doses. A kindling phenomenon has been described with cocaine in which neuronal function becomes altered with each dose of the drug. The psychosis is qualitatively very similar to a paranoid schizophrenic psychosis.[33] Although there is some controversy as to whether cocaine is associated with physical withdrawal on abrupt discontinuation, most clinicians feel that there is a characteristic syndrome of withdrawal effects, although they are not life-threatening.

AMPHETAMINE, METHAMPHETAMINE, AND OTHER STIMULANTS

According to the United Nations Office of Drugs and Crime, worldwide between 16 and 51 million people aged 15 to 64 used amphetamines-group substances at least once in 2007.[34] In the United States, people who reported that they had used methamphetamine in the previous month also dropped dramatically, from 529,000 people in 2007 to 314,000 in 2008.[3]

Street methamphetamine is referred to by many names, such as "speed," "meth," and "crank." Methamphetamine hydrochloride, clear chunky crystals resembling ice, can be inhaled by smoking. It is referred to as "ice," "crystal," and "glass" on the street.

The physiologic and psychologic effects of amphetamines and other stimulants are qualitatively similar to those of cocaine—they diminish fatigue, increase alertness, and suppress appetite. Pharmacologically, amphetamines increase the activity of catecholamine neurotransmitters (e.g., norepinephrine and dopamine) by increasing release and by inhibiting the degradative enzyme monoamine oxidase.[35] The longer duration of effect of methamphetamine has led to a shift away from cocaine and toward this longer-acting drug.

An analysis produced by the Rand Corporation[36] suggests that the economic cost of meth use in the United States reached $23.4 billion in 2005. Because of the difficulty in pinpointing the role of methamphetamine in crime, medical care and other factors, the RAND researchers gave a range of estimates, saying the overall toll may be as low as $16.2 billion or as high as $48.3 billion.[36]

These estimates include the burden of addiction, premature death, drug treatment, and many other costs associated with methamphetamine use. The RAND analysis found that nearly two thirds of the economic costs caused by methamphetamine use resulted from the burden of addiction and an estimated 900 premature deaths among users in 2005. For a sobering look at the methamphetamine epidemic in the United States the interested reader should view the full report.[36]

Methamphetamine is used orally, intranasally, rectally, by intravenous injection, and by smoking. Immediately after inhalation or intravenous injection, the methamphetamine user experiences an intense sensation, called a "rush" or "flash," that lasts only a few minutes and is described as extremely pleasurable.

PRESENTATION OF AMPHETAMINE INTOXICATION AND WITHDRAWAL

General

- Amphetamine intoxication is an acute condition that may result in death. Pharmacotherapy may be indicated for symptomatic control of seizures.
- Patients may experience withdrawal symptoms for several days, but are usually not in acute distress. Treatment is supportive in nature. Pharmacotherapy is not effective to treat the symptoms of amphetamine withdrawal.

Symptoms

- Depression, altered mental status, drug craving, dyssomnia, and fatigue are all symptoms of withdrawal.
- Amphetamine intoxication may present as increased wakefulness, increased physical activity, decreased appetite, increased respiration, hyperthermia, and euphoria. Other CNS effects include irritability, insomnia, confusion, tremors, convulsions, anxiety, paranoia, chest pain, and aggressiveness. Hyperthermia and convulsions can result in death.

Signs

- Patients with amphetamine intoxication may present with tachycardia, hypertension, or stroke.

Laboratory Tests

- A qualitative drug of abuse urine screening is used for diagnostic purposes. Confirmatory blood tests with gas chromatography and mass spectrophotometry may be used for verification.

Because methamphetamine elevates mood, people who experiment with it tend to use it with increasing frequency and in increasing doses, although this was not their original intent. The timing and intensity of the "rush" that accompanies the use of methamphetamine, which is a result of the release of high levels of dopamine in the brain, depends in part on the method of administration. Specifically, the effect is almost instantaneous when smoked or injected, whereas it takes approximately 5 minutes after snorting or 20 minutes after oral ingestion. Prolonged use of methamphetamine can result in a tolerance for the drug and increased use at higher dosage levels, creating dependence. Such continual use of the drug with little or no sleep may lead to an extremely irritable and paranoid state. Discontinuing use of methamphetamine often results in a state of depression, as well as fatigue, anergia, and some types of cognitive impairment that can last from 2 days to several months.

Both short- and long-term health effects have also been documented. Negative consequences of methamphetamine abuse range from anxiety and insomnia to convulsions, paranoia, and brain damage. Methamphetamine-induced caries, or "meth mouth" is a characteristic pattern of dental decay commonly observed in patients that smoke methamphetamine.[37]

In addition to the many direct effects on methamphetamine users are the indirect impacts on individuals and society. Flammable ingredients that include acetone, red phosphorous, ethyl alcohol, and lithium metal are used in methamphetamine cookers, often with disastrous results. Fires and explosions often ensue, resulting in severe burns and uncovering laboratories to local law

enforcement.[38] Children of methamphetamine abusers are at high risk of neglect and abuse, and pregnant women's use of methamphetamine can cause growth retardation, premature birth, and developmental disorders in neonates. Within this particular group, effective treatment for methamphetamine dependence can be one of the most important strategies in reducing the spread of HIV and other associated communicable diseases.[38] Treatment for methamphetamine dependence is very difficult, and has a low success rate.[39]

The expanding global market is fed by an increase in clandestine manufacture of methamphetamine. Not only are there more laboratories in more countries, but their size and sophistication are also increasing. The number of clandestine methamphetamine laboratories seized nationwide by the DEA increased from 263 in 1994 to 1,815 in 2000, a 590% increase.[40] In 2008, state and local police agencies seized almost 6,783 clandestine laboratories in the United States. So-called "kitchen" laboratories are still discovered, but today clandestine laboratories with 100-kg capacities per week are also found. Initially the clandestine manufacture of methamphetamine was based primarily in the West and Southwest.[40] Today methamphetamine can be found in cities across the United States, although local law enforcement pressures have caused a decrease in "superlaboratories" capable of producing at least 10 pounds per production cycle.[41] Unfortunately, increased methamphetamine production by Mexican drug cartels has offset the decreased domestic production.

Methamphetamine is manufactured using the ephedrine or pseudoephedrine reduction method. In this process, ephedrine or pseudoephedrine is extracted from OTC cold and allergy tablets. Pharmacists should be wary of persons wishing to purchase large quantities of products containing nonprescription sympathomimetic products. As a precaution, federal legislation now mandates that pseudoephedrine-containing products be kept behind a counter, and suitable identification must be shown before they can be purchased.

ECSTASY AND OTHER METHAMPHETAMINE ANALOGS

Several dozen analogs of amphetamine and methamphetamine are mildly hallucinogenic. Two methamphetamine analogs of most concern are 3,4-methylenedioxyamphetamine and especially 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy). Use of these compounds was particularly prevalent in the early 2000s. However, annual prevalence rates for ecstasy dropped considerably between 2000 and 2008, from 3.1% to 1.7% for 8th graders, from 5.4% to 2.9% for 10th graders, from 8.2% to 4.3% for 12th graders, from 9.1% to 3.7% among college students, and from 7.2% to 3.3% among young adults.[5]

The effects of MDMA usually last approximately 4 to 6 hours. Users of the drug say that it produces profoundly positive feelings, empathy for others, elimination of anxiety, and extreme relaxation. MDMA is also said to suppress the need to eat, drink, or sleep, enabling users to endure 2- to 3-day parties. Consequently, MDMA use sometimes results in severe dehydration or exhaustion. MDMA generally reduces inhibitions and creates a sense of euphoria, but it also can evoke anxiety and paranoia. Heavier doses generate depression, irrationality, and psychosis. Users claim they experience feelings of closeness with others and a desire to touch them.

MDMA use can result in a variety of acute psychiatric disturbances, including panic, anxiety, depression, and paranoid thinking.[37] Physical symptoms include muscle tension, nausea, blurred vision, faintness, chills, and sweating. MDMA also increases the heart rate and blood pressure. Other effects include hyperthermia, dehydration, vomiting, tremors, loss of control over body movements, insomnia, convulsions, rapid eye movements, and teeth and jaw clenching.

MDMA is perceived to be a harmless drug by many of its users, based in part on the fact that the risk of death is low compared with other drugs such as heroin and cocaine. However, mounting evidence points to neurotoxic effects of MDMA, involving a complex and incompletely understood mechanism. MDMA has been clearly shown to destroy serotonin-producing neurons in animals.[42] Doses of MDMA that produce neurotoxicity are only 2 or 3 times more than the minimum dose needed to produce a psychotropic response.

Researchers have found that heavy MDMA users have memory problems that persist for at least 2 weeks after they have stopped using the drug.[43] McCann and colleagues[44,45] conducted several studies to determine the effects of MDMA use on cognitive performance. MDMA users and controls were found to perform similarly on several cognitive tasks. However, MDMA subjects had significant performance deficits on a sustained-attention task requiring arithmetic calculations, a task requiring complex attention and incidental learning, a task requiring short-term memory, and a task of semantic recognition and verbal reasoning. The authors believe that their data provide further evidence that MDMA is neurotoxic to brain serotonin neurons in humans, and the behavioral data suggest that brain serotonin injury is associated with subtle but significant cognitive deficits.

Manufacturers of illicit drugs sometimes substitute other, potentially more dangerous substances for the one the buyer is expecting. Other suppliers produce products adulterated with chemical byproducts of the incomplete processing of active ingredients. One such chemical, *para*-methoxyamphetamine, is a drastically more potent hyperthermic agent than MDMA. Deaths from this chemical have been reported.[46]

HALLUCINOGENS

The drugs commonly classified as hallucinogens are lysergic acid diethylamide (LSD), psilocybin, dimethyltryptamine (DMT), mescaline, and other related compounds. LSD is one of the most potent mood-changing chemicals. It is manufactured from lysergic acid, which is found in ergot, a fungus that grows on rye and other grains.

Pharmacologically, LSD and related drugs stimulate both presynaptic (5-hydroxytryptamine [HT]$_{1A}$ and 5-HT$_{1B}$) and postsynaptic (5-HT$_2$) serotonin receptors in the brain, which functionally can cause either agonist or antagonist effects on serotonin activity.[48] Precisely how the hallucinogens exert their effects remains unclear. LSD is an extraordinarily potent compound, producing observable CNS effects at doses as low as 25 mcg.

LSD is sold on the street in tablets, capsules, and occasionally in liquid form. It is odorless, colorless, and tasteless and usually is taken by mouth. Often LSD is added to absorbent paper, such as blotter paper, and divided into small decorated squares, with each square representing one dose.

The effects of LSD are unpredictable. They depend on the amount taken; the user's personality, mood, and expectations; and the surroundings in which the drug is used. Usually the user feels the first effects of the drug 30 to 90 minutes after taking it. The physical effects include dilated pupils, higher body temperature, increased heart rate and blood pressure, sweating, loss of appetite, sleeplessness, dry mouth, and tremors.

Sensations and feelings change much more dramatically than the physical signs. The user can feel several different emotions at once or swing rapidly from one emotion to another. If taken in a large enough dose, the drug produces delusions and visual hallucinations. The user's sense of time and self changes. Sensations can seem to "cross over," giving the user the feeling of hearing colors and seeing sounds.

Many LSD users experience flashbacks, or recurrence of certain aspects of a person's experience, without the user having taken the drug again. A flashback occurs suddenly, often without warning, and can occur within a few days or more than a year after LSD use. Flashbacks usually occur in people who use hallucinogens chronically or have an underlying personality problem; however, otherwise healthy people who use LSD occasionally also can have flashbacks.

Most users of LSD voluntarily decrease or stop its use over time. LSD is not considered an addictive drug because it does not produce compulsive drug-seeking behavior. However, as with many of the addictive drugs, LSD use produces tolerance, so some users who take the drug repeatedly must take progressively higher doses to achieve the state of intoxication that they had achieved previously.

Psychologic symptoms of intoxication include a subjective intensification of perceptions, depersonalization, illusions, hallucinations, and synesthesias, the overflow of one sensory modality to another. LSD is the most potent and longest-acting hallucinogen; it is hundreds of times more potent than both psilocybin and mescaline. DMT is inactive when ingested orally but can be smoked, inhaled, or injected. There is cross-tolerance among LSD, psilocybin, and mescaline. There is no observable physical withdrawal syndrome after abrupt discontinuation of hallucinogenic drugs. Complications from hallucinogen use are primarily psychologic. Users sometimes experience prolonged episodes of panic—the so-called "bad trip." The flashbacks noted above are common, occurring in approximately 15% of users and occurring episodically up to several years after the last exposure to the drug. Flashbacks can occur spontaneously but are also triggered by other drugs, including marijuana, and by anxiety-provoking stimuli. Contrary to a widely held notion in the 1960s and early 1970s, there is no reliable evidence that hallucinogen use causes chromosome damage or genetic defects.

MARIJUANA

Marijuana, referred to as "reefer," "pot," "grass," or "weed," was the most commonly used illict drug in 2008. Among persons aged 12 or older, the rate of past month marijuana use in 2008 (6.1%) was similar to the rate in 2007 (5.8%).[5] Of those, 54.5% used only marijuana, and 19.6% used marijuana and another illicit drug.[5] In 2008, marijuana was used by 75.7% of current illicit drug users and was the only drug used by 57.3% of them.[5] The rate of marijuana use for youth, while well off peak levels of the late 1990s, has edged up in the past year. According to the most recent Monitoring for the Future study, among 12th-graders 20.6% said they used it within the *past month*, compared with 19.4% in 2008 and 18.3% in 2006. Among 10th-graders, pot use in the past month rose to 15.9% this year from 13.8% in 2008. In the *past year*, the share of 8th-graders who smoked marijuana was 11.8%, compared with 10.9% in 2008. Tenth-graders' use was 26.7% this year and 23.9% in 2008. The percentage of 12th-graders was 32.8% compared with 32.4% in 2008.

Most users smoke marijuana in hand-rolled cigarettes (joints), while some use pipes or water pipes (bongs). Marijuana cigars called blunts have also become popular.[47] To make blunts, users slice open cigars and replace the tobacco with marijuana. Marijuana also is used to brew tea and is sometimes mixed into foods.

Marijuana's effects begin immediately after the drug enters the brain and last from 1 to 3 hours. If marijuana is consumed in food or drink, the short-term effects begin more slowly, usually in 30 minutes to 1 hour, and last longer, for as long as 4 hours. Smoking marijuana delivers several times more of its major active ingredient, delta-9-tetrahydrocannabinol (THC) into the blood than does eating or drinking the drug.[48]

PRESENTATION OF MARIJUANA INTOXICATION

General Symptoms

- Patients intoxicated with marijuana may experience euphoria, sensory intensification, increased appetite, apathy, hallucinations, and dry mouth. Occasionally, marijuana use produces anxiety, fear, distrust, or panic.

Signs

- Tachycardia and conjunctival congestion may be observed in patients intoxicated with marijuana.

Laboratory Tests

- Although the duration of effect of marijuana may only be several hours, THC is detectable on toxicologic screening for up to 4 to 5 weeks, especially in chronic users.

Marijuana use impairs a person's ability to form memories, recall events, and shift attention from one thing to another. THC also disrupts coordination and balance by binding to receptors in the cerebellum and basal ganglia. Through its effects on the brain and body, marijuana intoxication can cause accidents. Studies show that approximately 6% to 11% of fatal accident victims test positive for THC. In many of these cases alcohol is detected as well.[49]

The principal psychoactive component of marijuana is THC. Hashish, the dried resin of the top of the plant, is much more potent than the plant itself. Increasingly sophisticated growing techniques have resulted in plants of greater potency. The average potency of marijuana increased in 2007 to the highest levels ever recorded, likely because of increased demand for higher-potency marijuana and improvements in cultivation techniques. According to University of Mississippi School of Pharmacy Potency Monitoring Project data, the average THC content in tested samples of marijuana in 2007 increased to the highest level ever recorded—9.64% in 2007, rising from 8.77% in 2006. The average THC content for hashish was 24.41% in 2008. Indoor cannabis cultivation is most prevalent in western states; however, indoor cultivation in eastern states, particularly Florida and Georgia, increased sharply in 2007.[40]

Marijuana has been used widely and is believed by many to be a relatively harmless, nonaddictive intoxicant. Chronic low doses of marijuana usually are not associated with significant physical withdrawal on abrupt discontinuation, but many chronic users exhibit compulsive drug-seeking and drug-use behaviors characteristic of addiction or dependence. Acutely, marijuana has many of the effects of alcohol—sedation, a decrease in reactivity and ability to perform complex tasks, and disinhibition. Chronic use is associated with all the risks of tobacco smoking, although marijuana smokers are commonly also tobacco smokers, and thus differentiation of effects is often difficult. Endocrine effects including amenorrhea, decreased testosterone production, and inhibition of spermatogenesis have been demonstrated. Marijuana is associated with an amotivational syndrome characterized by a behavioral pattern of apathy, dullness, impaired judgment, decreased concentration and memory, loss of interest in personal hygiene, and a general reduction of goal-directed behavior.[50]

Marijuana smoke is irritating to the lungs. Researchers have found that the daily use of one to three marijuana joints appears to produce approximately the same lung damage and potential cancer risk as smoking 5 times as many cigarettes.[51] The study results suggest that the way smokers inhale marijuana, in addition to its chemical composition, increases the adverse physical effects. The study findings refute the argument that marijuana is safer than tobacco because users smoke only a few joints a day.

Clearly, there is much more work to be done before the precise health and psychologic effects of marijuana use are well understood. In fact, many of these health issues remain the subject of

much debate. Undoubtedly, opinions on its risks are polarized along the lines of proponents' views on what its legal status should be. This polarization of opinion has prevented the development of any consensus on what health information the medical profession should give to patients who are users or potential users of marijuana. There is conflicting evidence about many of the effects of marijuana use. Readers are referred to two excellent articles that attempt to summarize in a dispassionate way the evidence on the most probable adverse health and psychologic consequences of acute and chronic use of marijuana.[52,53]

CLINICAL CONTROVERSY

The mere mention of the words "medical marijuana" is bound to evoke strong emotions among laypersons and healthcare professionals alike. While the federal government continues to enforce laws that make possession and use of marijuana illegal, regardless of the intended purpose, at last count 13 of the U.S. states have legalized medical marijuana. While the safety and efficacy of marijuana to treat certain identifiable medical conditions has been confirmed, many other uses are supported by anecdote or limited clinical experience. However, the debate involves much more than whether cannabis works or not to treat illness. Instead, there are political, social, economic, and religious considerations that cloud the controversy over whether marijuana should be legalized for medical purposes. This debate is bound to continue for years to come.

INHALANTS

Inhalants are a diverse group of substances that include volatile solvents, gases, and nitrites that are sniffed, snorted, huffed, or bagged to produce intoxicating effects similar to those of alcohol. These substances are found in common household products such as glues, lighter fluid, cleaning fluids, paint products, nail polish remover, gasoline, rubber glue, waxes, and varnishes. Chemicals found in these products include toluene, benzene, methanol, methylene chloride, acetone, methylethyl ketone, methylbutyl ketone, trichloroethylene, and trichloroethane. The gas used as a propellant in canned whipped cream and in small metallic containers called "whippets" (used to make whipped cream) is nitrous oxide or "laughing gas." Tiny cloth-covered ampules called "poppers" or "snappers" by abusers contain amyl nitrite, a medication used to dilate blood vessels. Butyl nitrite, sold as tape head cleaner and referred to as "rush," "locker room," or "climax," is often sniffed or huffed to get high.

Inhalants can be sniffed directly from an open container or huffed from a rag soaked in the substance and held to the face. Alternatively, the open container or soaked rag can be placed in a bag where the vapors can concentrate before being inhaled. Although inhalant abusers might prefer one particular substance because of taste or odor, a variety of substances can be used because of similar effects, availability, and cost. Once inhaled, the extensive capillary surface area of the lungs allows rapid absorption of the substance, and blood levels peak rapidly. Entry into the brain is fast, and the intoxicating effects are intense but short lived. Intoxication is often accompanied by headache and nausea, and users can experience hallucinations and delusions. The most serious physical risk of acute use is sudden death, usually from cardiac arrhythmias. Some users die from suffocation by plastic bags that contain the solvent. With chronic use, the drugs are toxic to virtually all organ systems. Psychologic impairment; impaired pulmonary, renal, and hepatic function; neuropathies; encephalopathy; and brain damage have all been observed.

Inhalants depress the CNS, producing decreased respiration and blood pressure. Users report distortion in perceptions of time and space. Many users experience headaches, nausea, slurred speech, and loss of motor coordination. A rash around the nose and mouth can be seen, and the abuser can start wheezing. An odor of paint or organic solvents on clothes, skin, and breath is sometimes a sign of inhalant abuse. Other indicators of inhalant abuse include slurred speech or staggering gait; red, glassy, watery eyes; and excitability or unpredictable behavior.

TREATMENT

Substance-Related Disorders

ACUTE DRUG INTOXICATIONS

Treatment of drug intoxication, summarized in Table 74–2, is primarily supportive. Vital functions are maintained while waiting for the drug to be eliminated. Whenever possible, drug therapy should be avoided because psychotropic drug therapy has the potential for worsening a toxic reaction to another psychoactive

TABLE 74-2 Pharmacologic Treatment of Substance Intoxication

Drug Class	Nonpharmacologic Therapy	Pharmacologic Therapy	Level of Evidence[a,b]
Benzodiazepines	Support vital functions	Flumazenil 0.2 mg/min IV initially, repeat up to 3 mg max.	AI
Alcohol, barbiturates, and sedative-hypnotics (nonbenzodiazepines)	Support vital functions	None	B3
Opiates	Support vital functions	Naloxone 0.4–2 mg IV every 3 min	A1
Cocaine and other CNS stimulants	Monitor cardiac function	Lorazepam 2–4 mg IM every 30 min to 6 h as needed for agitation	B2
		Haloperidol 2–5 mg (or other antipsychotic agent) every 30 min to 6 h as needed for psychotic behavior	B3
Hallucinogens, marijuana, and inhalants	Reassurance; "talk-down therapy"; support vital functions	Lorazepam and/or haloperidol as above	B3
Phencyclidine	Minimize sensory input	Lorazepam and/or haloperidol as above	B3

[a]Strength of recommendations, evidence to support recommendation, A, good; B, moderate; C, poor.
[b]Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.
Data from O'Brien,[16] Fudala et al.,[54] Smith and Seymour,[68] and Knapp et al.[69]

agent; however, when patients are agitated, combative, assaultive, hallucinating, or delusional, drug therapy may be required. Toxicology screens are useful in the evaluation and treatment process, but knowledge of the metabolism of the suspected drug and its excretion patterns is important for proper interpretation of test results. When toxicology screens are desired, blood or urine should be collected immediately upon the patient's arrival.

For alcohol and barbiturate intoxication, supportive treatment is the rule. For benzodiazepine intoxication, the benzodiazepine antagonist flumazenil can be used to reverse toxic effects. In the case of opiate intoxication, if the patient is unconscious and respiration is depressed, the opiate antagonist naloxone can be used to revive the patient. The usual dosage for naloxone in acute opiate toxicity is 0.4 to 2 mg intravenously, given approximately every 3 minutes as necessary. Although naloxone is effective in reversing opiate overdose, it also can precipitate physical withdrawal in physically dependent patients.

Intoxication with stimulants, including cocaine, is treated pharmacologically only if the patient is overtly psychotic and agitated.[55,56] Injectable benzodiazepines, usually lorazepam 2 to 4 mg intramuscularly every 30 minutes to 6 hours as necessary, can be used for agitation. As a backup to lorazepam, antipsychotic drugs can be used on a short-term basis, primarily in patients with psychotic symptoms, and usually at relatively low doses, such as haloperidol 2 to 5 mg intramuscularly every 30 minutes to 6 hours as necessary, followed by 5 to 15 mg orally per day in single or divided doses if the patient is still psychotic after initial treatment.[56]

A recent evidence-based guideline gives precise recommendations for treating the cardiovascular complications of cocaine abuse and provides insight into the epidemiology, pathophysiology, treatment, and prognosis of the cardiac effects of cocaine.[57] Seizures generally are treated supportively. Intravenous lorazepam or diazepam can be used if seizures progress to status epilepticus.[56]

Hallucinogen intoxication is treated in a manner similar to stimulant intoxication. Drug therapy often can be avoided because patients can respond to careful reassurance, or so-called talk-down therapy. When necessary, short-term antianxiety and/or antipsychotic drug therapy can be used, as described previously.

WITHDRAWAL

3 Treatment of drug withdrawal is the primary indication for drug therapy in substance-related disorders. Goals of drug therapy include prevention of progression of withdrawal to life-threatening severity, and enabling the patient to be sufficiently comfortable and functional to participate in a behavioral treatment program and supportive drug therapy. The clinician should remember that withdrawal is usually part of a substance dependence disorder. In drug therapy for withdrawal, it is important to avoid reinforcing the patient's drug-seeking and drug-use behavior to the extent possible. Patients must be educated to deal with the stress of withdrawal without seeking drugs. A recent review on the management of drug and alcohol withdrawal has been published.[13] Treatment of drug withdrawal is summarized in Table 74–3.

TABLE 74-3 Treatment of Withdrawal from Some Common Drugs of Abuse

Drug or Drug Class	Pharmacologic Therapy	Level of Evidence[a,b]
Benzodiazepines		
Short to intermediate acting	Lorazepam 2 mg 3–4 times a day; taper over 5–7 days	A1
Long-acting	Lorazepam 2 mg 3–4 times a day; taper over additional 5–7 days	A1
Barbiturates	Pentobarbital tolerance test; initial detoxification at upper limit of tolerance test; decrease dosage by 100 mg every 2–3 days	B3
Opiates	Methadone 20–80 mg orally daily; taper by 5–10 mg daily or buprenorphine 4–32 mg orally daily, or clonidine 2 mcg/kg 3 times a day × 7 days; taper over additional 3 days	A1 (methadone and buprenorphine) B1 (clonidine)
Mixed-substance withdrawal		
Drugs are cross-tolerant	Detoxify according to treatment for longer-acting drug used	B3
Drugs are not cross-tolerant	Detoxify from one drug while maintaining second drug (cross-tolerant drugs), then detoxify from second drug	B3
CNS stimulants	Supportive treatment only; pharmacotherapy often not used; bromocriptine 2.5 mg 3 times a day or higher may be used for severe craving associated with cocaine withdrawal	B2

[a]Strength of recommendations, evidence to support recommendation, A, good; B, moderate; C, poor.
[b]Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.
Data from O'Brien,[16] DHHS,[62] and Gorelick.[65]

CNS DEPRESSANT WITHDRAWAL

Benzodiazepines

3 Treatment of benzodiazepine withdrawal is very similar to the treatment of alcohol withdrawal. The major difference in management is the length of treatment. The onset of withdrawal symptoms in patients physically dependent on the long-acting benzodiazepines can be delayed up to 7 days after discontinuation of the drug.[16] A common approach in detoxification of such patients is to initiate treatment at usual dosages (chlordiazepoxide orally 50 mg 3 times a day; lorazepam orally 2 mg 3 times a day) and to maintain the initial dosage for 5 days, with gradual tapering over an additional 5 days. Detoxification in patients physically dependent on shorter-acting benzodiazepines is similar to treatment of alcohol withdrawal.

Among the benzodiazepines, alprazolam has been suggested to be more difficult to taper and discontinue than the other benzodiazepines. A longer, more gradual taper of the benzodiazepine used for detoxification can be needed. With all benzodiazepines, protracted minor abstinence symptoms—such as anxiety, insomnia, irritability, sensitivity to light and sound, and muscle spasms—can remain for several weeks in patients with a history of long exposure, even after the acute phase of benzodiazepine withdrawal is complete.

Barbiturates and Other Sedative-Hypnotic Drugs

3 Although once used extensively, barbiturates and other nonbenzodiazepine sedating medications have been largely replaced by safer and more effective medications. Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways. Withdrawal from barbiturates should be handled similarly to interventions for

the abuse of alcohol and benzodiazepines.[16] Specific recommendations have been suggested for zolpidem withdrawal.[15]

Opiates

Opiate withdrawal syndrome is similar to a severe case of influenza. It is not life-threatening unless there is a concurrent life-threatening medical condition. Although most patients complain of symptoms of withdrawal such as cramping or insomnia, these symptoms are tolerable, and initiation of drug therapy can be avoided in many cases. Observable signs of withdrawal should be noted before initiation of drug therapy. Characteristic signs and symptoms of opiate withdrawal include pupillary dilatation, lacrimation, rhinorrhea, piloerection ("gooseflesh"), yawning, sneezing, anorexia, nausea, vomiting, and diarrhea. Seizures do not occur. Onset and duration of withdrawal symptoms and the time of peak occurrence depends on the half-life of the drug involved. Typically heroin withdrawal reaches a peak within 36 to 72 hours of discontinuation and can last for 7 to 10 days. For methadone, symptoms peak at 72 hours but can last for 2 weeks or more.[16]

In the past drug therapy for opioid withdrawal had typically been methadone, a synthetic opiate. Methadone is administered in decreasing doses over a period not exceeding 30 days (short-term detoxification) or 180 days (long-term detoxification). In 2009, a systematic review[58] including 1907 people from twenty trials was reported. The purpose of this report was to evaluate the effectiveness of tapered methadone compared with other detoxification treatments and placebo in managing opioid withdrawal on completion of detoxification and relapse rate. Comparing methadone versus any other pharmacological treatment (e.g., adrenergic agonists [11 studies], other opioid agonists [four studies], chlordiazepoxide [one study]) the authors found no clinical difference between the two treatments in terms of completion of treatment, relative risk (RR) 1.08 (95% CI, 0.95–1.24) and results at follow-up RR 1.17 (95% CI, 0.72–1.92). The studies included in this review confirm that slow tapering with temporary substitution of long acting opioids, can reduce withdrawal severity. Nevertheless the majority of patients relapsed to heroin use.[58]

Usually, opioid dependency is treated initially with detoxification. In the past, opioid-dependent patients relied on methadone or levo-alpha-acetylmethadol, but federal restrictions limited distribution of these drugs to a small number of methadone clinics. There were limited provisions for take-at-home dosing of methadone because of concern about the diversion of these drugs to illicit use.

USE OF BUPRENORPHINE IN OPIATE WITHDRAWAL AND MAINTENANCE

In 2002, buprenorphine was approved for opioid withdrawal. Prior to the passage of the federal Drug Addiction Treatment Act (DATA) of 2000,[59] office-based management of opioid dependence was illegal because existing federal laws prohibited physicians from prescribing narcotics for the sole purpose of maintaining a patient in a narcotic-addicted state.

The first of two formulations approved, Subutex, contains only buprenorphine and is intended for use at the beginning of treatment. The other, Suboxone, contains both buprenorphine and the opiate antagonist naloxone, and is intended to be used in maintenance treatment of opiate addiction. When buprenorphine with naloxone is administered sublingually, the naloxone component produces no clinically significant effect; however, after parenteral administration, naloxone-induced opioid antagonism occurs resulting in symptoms of withdrawal.[60,61]

To qualify, physicians must be board certified in addiction medicine/psychiatry or hold other special credentials, and physicians are required to obtain 8 hours of authorized training before they can prescribe medications for office-based treatment of opioid dependence.[60] DATA 2000, as amended in December 2006, specifies that an individual physician may have a maximum of 30 patients on opioid therapy at any one time for the first year. One year after the date on which a physician submitted the initial notification, the physician may submit a second notification of the need and intent to treat up to 100 patients.[60]

The goal of using buprenorphine for medically supervised withdrawal from opioids is to provide a transition from the state of physical dependence on opioids to an opioid-free state, while minimizing withdrawal symptoms (and avoiding side effects of buprenorphine).[61]

Medically supervised withdrawal with buprenorphine consists of an induction phase and a dose-reduction phase. Best practice guidelines collectively called Treatment Improvement Protocols (TIPs) are periodically issued for treatment of substance use disorders. TIP 40 (the guideline for the Use of Buprenorphine in the Treatment of Opioid Addiction),[62] provides consensus- and evidence-based guidance on the use of buprenorphine.

The statement recommends that patients dependent on short-acting opioids (e.g., hydromorphone, oxycodone, heroin) be inducted directly onto buprenorphine/naloxone tablets. The use of buprenorphine (either as buprenorphine monotherapy or buprenorphine/naloxone combination treatment) to taper off long-acting opioids should be considered only for those patients who have evidence of sustained medical and psychosocial stability, and should be undertaken in conjunction and in coordination with patients' overall opioid treatment programs. Induction protocols are shown in Figure 74–2.

Maintenance treatment with buprenorphine for opioid addiction consists of three phases: (1) induction, (2) stabilization, and (3) maintenance.[62] Induction is the first stage of buprenorphine treatment and involves helping patients begin the process of switching from the opioid of abuse to buprenorphine. The goal of the induction phase is to find the minimum dose of buprenorphine at which the patient discontinues or markedly diminishes use of other opioids and experiences no withdrawal symptoms, minimal or no side effects, and no craving for the drug of abuse. The consensus panel recommends that the buprenorphine/naloxone combination be used for induction treatment (and for stabilization and maintenance) for most patients. The consensus panel further recommends that initial induction doses be administered as observed treatment; further doses may be thereafter provided via prescription. To minimize the chances of precipitating withdrawal, patients who are transferring from long-acting opioids (e.g., methadone, sustained-release morphine, sustained-release oxycodone) to buprenorphine should be inducted using buprenorphine monotherapy, but switched to buprenorphine/naloxone soon thereafter.

The stabilization phase begins when a patient is experiencing no withdrawal symptoms, is experiencing minimal or no side effects, and no longer has uncontrollable cravings for opioid agonists. Dosage adjustments may be necessary during early stabilization, and frequent contact with the patient increases the likelihood of compliance. The longest period that a patient is on buprenorphine is the maintenance phase. This period may be indefinite. During the maintenance phase, attention must be focused on the psychosocial and family issues that have been identified during the course of treatment as contributing to a patient's addiction.[62]

Some other issues related to opioid abuse that need to be addressed during maintenance treatment include, but are not limited to, the following:[62]

- Psychiatric comorbidity
- Somatic consequences of drug use
- Family and support issues
- Structuring of time in prosocial activities

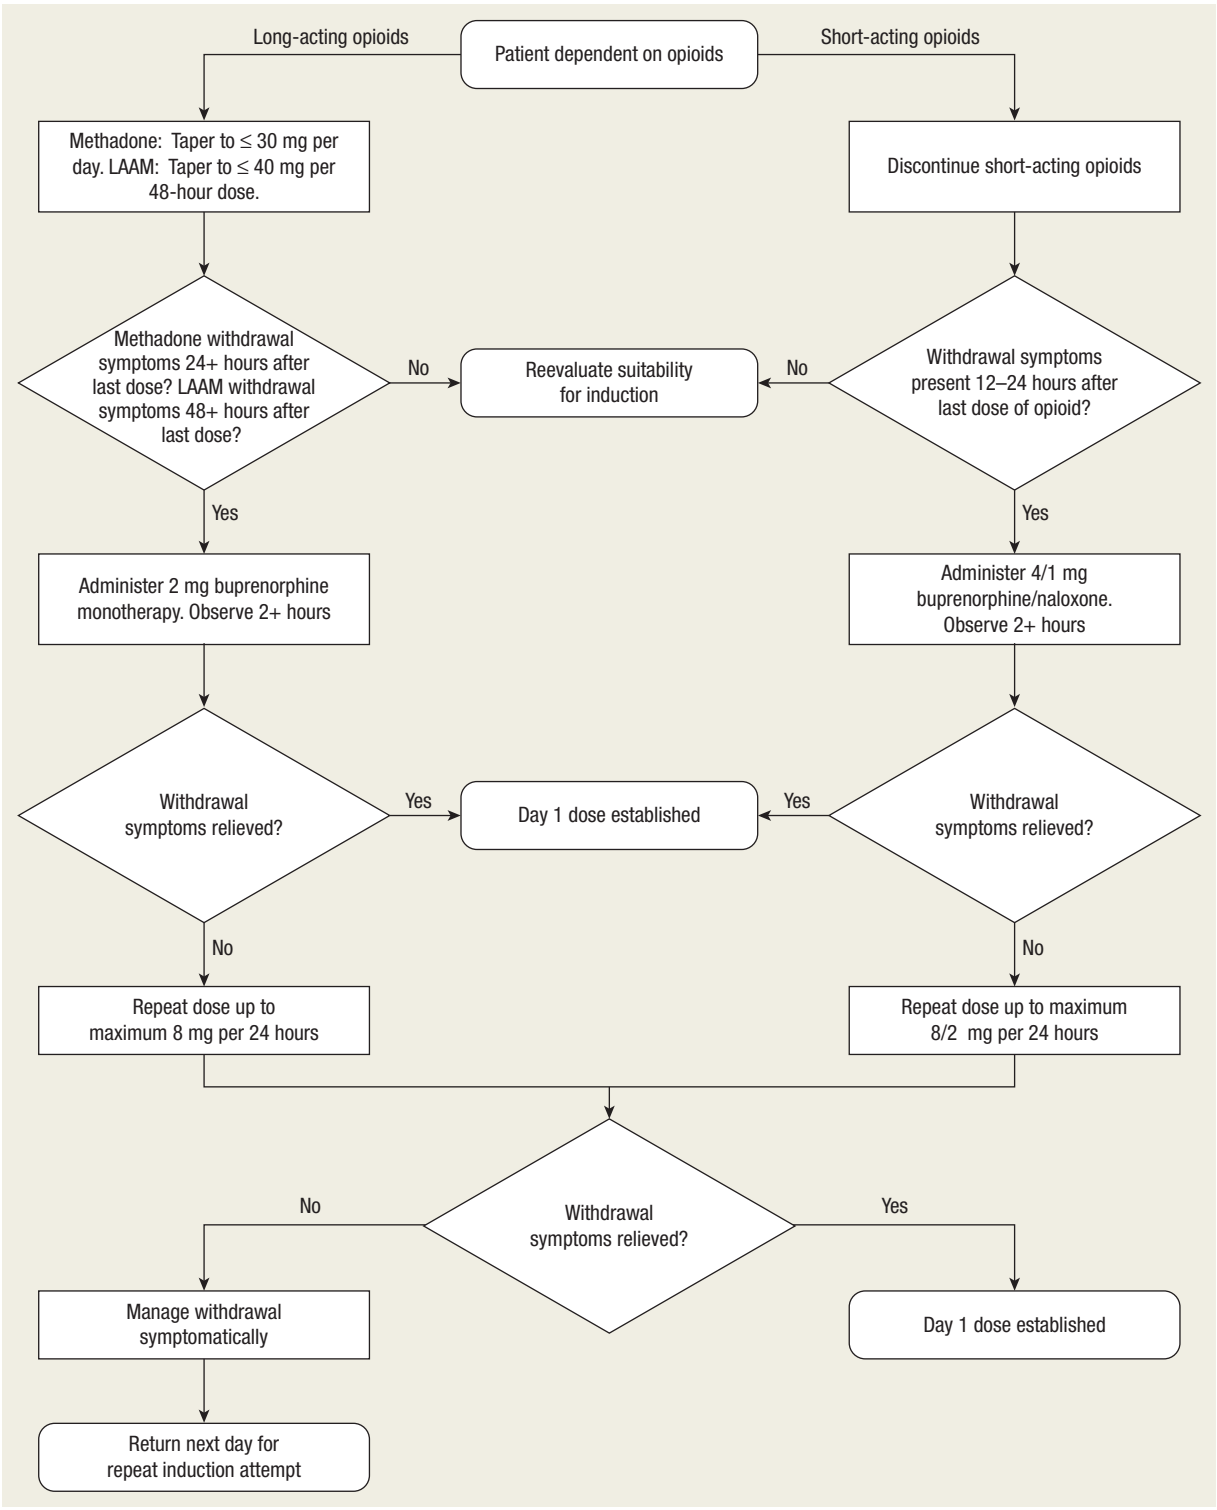

FIGURE 74-2. Determining the induction dose for days 1 to 2 of buprenorphine therapy. *(From reference 62.)*

- Employment and financial issues
- Legal consequences of drug use
- Other drug and alcohol abuse

A recent systematic review[63] evaluating the withdrawal component of buprenorphine treatment, including twenty-two studies involving 1,736 participants, was published. The major comparisons for buprenorphine were with methadone (5 studies) and clonidine or lofexidine (12 studies). Five studies compared different rates of buprenorphine dose reduction.

The authors concluded that severity of withdrawal is similar for withdrawal managed with buprenorphine and withdrawal managed with methadone, but withdrawal symptoms may resolve more quickly with buprenorphine. It appears that completion of withdrawal treatment may be more likely with buprenorphine relative to methadone (RR 1.18; 95% CI, 0.93–1.49; $P = 0.18$) but more studies are required to confirm this.[63]

A rapid detoxification technique has been developed that is designed to shorten detoxification by precipitating withdrawal through the administration of opioid antagonists such as naloxone

or naltrexone.[64] This approach is thought to have the advantage of getting patients through detoxification rapidly, minimizing the risk of relapse, and initiating treatment more quickly with naltrexone maintenance combined with suitable psychosocial interventions. Ultrarapid detoxification represents a variant of this technique in which patients undergo opioid antagonist–precipitated withdrawal while under general anesthesia or heavy sedation. In the United States, there has been a rapid proliferation of programs offering ultrarapid detoxification, with some programs charging up to $15,000 per treatment.[64] Rapid detoxification remains unproven and controversial.

WITHDRAWAL FROM OTHER SUBSTANCES

Withdrawal from other drugs, including cocaine and other stimulants, is primarily supportive. However, pharmacotherapy recently has assumed a greater role in treating cocaine withdrawal and dependence. Bromocriptine, a dopamine antagonist at low dosages and an agonist at high dosages, is usually used in the treatment of parkinsonism and hyperprolactinemia and has been used to treat cocaine withdrawal symptoms and to reduce the craving for cocaine. Use of bromocriptine is based on the hypothesis that chronic use of cocaine causes dopamine depletion; therefore higher dosages should be used (i.e., 2.5 mg 3 times daily or higher). Despite initially promising pilot studies, recent evidence does not support the efficacy of bromocriptine to reduce cocaine use or craving.[65]

A more recent approach is the use of the cocaine vaccine that treats cocaine dependence. In the presence of the vaccine, the immune system forms antibodies that prevent cocaine from crossing the blood-brain barrier, blocking access to receptor sites in the brain. A recently published randomized, double-blind, placebo-controlled efficacy trial showed that a vaccine can prevent addicts from getting high by blocking the drug's effect on the brain, though it apparently does not blunt cravings for the drug.[66]

In this study, the vaccine had only limited success because it produced a suboptimal immune response in many patients. Those who reached the target antibody levels had significantly more cocaine-free urine samples than the others between the 9th and 16th weeks of the 6-month study, and 53% of them reduced their cocaine use by half, compared with only 23% in the group that was vaccinated but did not produce sufficient antibodies.[67]

SUBSTANCE DEPENDENCE

(2) The treatment of drug dependence is primarily behavioral. The patient generally is taught that complete abstinence is the only realistic alternative to a life of uncontrollable drug use and despair that ultimately will end in death, and that there is no intermediate, controllable level of drinking or use of another drug. There may be an extremely few individuals who can return to controllable levels of drinking alcohol, but it is impossible to predict who these individuals are. The prospect of life without alcohol or other drugs is incomprehensible to many patients. Entry into treatment often is facilitated by some type of leverage that the drug-dependent person associates with negative consequences, such as potential loss of job, divorce, legal problems, or deteriorating physical health. Early treatment is directed at penetrating the denial of a problem that is always present. The patient must be educated as to the disease of addiction, the effects of drugs, and the permanence of the condition.

As evidenced by the approval of the two buprenorphine products, there has been a trend toward outpatient treatment for drug dependence, caused in part by cost-containment efforts. Inpatient treatment programs can cost as much as $20,000 for a 4-week stay. When withdrawal symptoms are mild to moderate and there are no other medical indications for hospitalization, outpatient treatment can be an attractive alternative to inpatient treatment. One critical criterion for outpatient treatment is the patient's compliance with complete abstinence from the dependence-producing drug during the treatment experience.

Families must be involved in treatment. The course of the patient's illness often has a devastating effect on other family members. Severely depleted self-esteem, denial of the family member's addiction, feelings of responsibility for the family member's drug use, and other behaviors that parallel the addiction process are often present.

(4) Treatment must be a lifelong process. Aftercare, or what is now being called *continued care,* should include regular and frequent treatment in some form. Most drug-dependence treatment programs embrace a treatment approach based on the twelve steps to recovery. Among chemically dependent healthcare professionals, treatment that incorporates both 12-step and peer-led self-help groups can be most effective.

CONCLUSIONS

Substance use disorders remain one of the great public health issues of contemporary society. Dependence on drugs is a powerful emotional and political issue. Because we live in a chemically oriented society, everyone is affected in some way by drug abuse and drug dependence. Healthcare professionals must be particularly vigilant for problems associated with drug use, not only for our patients, but also for ourselves.

CHAPTER 75

Substance-Related Disorders: Alcohol, Nicotine, and Caffeine

PAUL L. DOERING AND ROBIN MOORMAN LI

KEY CONCEPTS

1. Tobacco is the number 1 preventable cause of death in the United States.
2. Between 12 and 16 million Americans report current heavy alcohol use or alcohol abuse.
3. Pharmacogenomics studies have identified genotypic and functional phenotypic variants that either serve to protect patients or predispose them toward alcohol dependence.
4. Alcohol is a central nervous system depressant that shares many pharmacologic properties with the nonbenzodiazepine sedative hypnotics.
5. The metabolism of alcohol is considered to follow zero-order pharmacokinetics, and this has important implications for the time course in which alcohol can exert its effects.
6. Benzodiazepines are the treatment of choice for alcohol withdrawal.
7. Disulfiram, naltrexone, and acamprosate are FDA-approved drug therapies for the treatment of alcohol dependence. The clinical utility of these agents to improve sustained abstinence remains controversial. Relapse is common.
8. More than three quarters of smokers are nicotine dependent. Tobacco dependence is a chronic condition that requires repeated interventions.
9. Use of nicotine replacement therapy along with behavioral counseling doubles cessation rates.
10. Bupropion and varenicline are efficacious alone and in combination with nicotine replacement therapy for smoking cessation.
11. Special precautions are associated with the use of varenicline for smoking cessation.
12. Caffeine's pharmacologic actions are similar to those of other stimulant drugs. As such, abstinence from caffeine induces a distinct withdrawal syndrome that includes headache, drowsiness, and fatigue.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

KEY MEDICAL TERMS

Caffeinism: Caffeinism is the term coined to describe the clinical syndrome produced by acute or chronic overuse of caffeine.

Euphoria: A mood state characterized by an exaggerated, superficial sense of well-being, characterized by extreme happiness, sometimes more than is reasonable in a particular situation.

Intoxication: The development of a substance-specific syndrome after recent ingestion and presence in the body of a substance; and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system.

Withdrawal: The development of a substance-specific physiologic syndrome after cessation of or reduction in intake of a substance that was used regularly.

1 Alcohol, nicotine, and caffeine are considered by most to be socially acceptable drugs, yet they impose an enormous social and economic cost on our society. Approximately 443,000 deaths each year are attributable to tobacco use, making tobacco the number 1 preventable cause of death and disease in this country.[1,2] The three leading causes of death attributable to smoking include lung cancer, chronic obstructive pulmonary disease, and ischemic heart disease.[3]

2 In 2008, heavy drinking was reported by 6.9% of the population aged 12 or older, or 17.3 million people.[4] More than one fifth (23.3%) of persons aged 12 or older participated in binge drinking at least once in the 30 days prior to the National Survey on Drug Use and Health in 2008. The World Health Organization estimates that there are approximately 2 billion people worldwide who consume alcoholic beverages, and 76.3 million with diagnosable alcohol-use disorders.[5] Long-term alcohol abuse often leads to chronic disease. A causal relationship between alcohol abuse and at least 60 types of chronic disease or injury have been established (e.g., esophageal cancer, liver cancer, and cirrhosis of the liver, epileptic seizures, homicide, and motor vehicle accidents) worldwide.[5] Nationally, according to the Drug Abuse Warning Network 2006 survey, 577,521 emergency department (ED) visits involved either alcohol in combination with another drug (all ages) or alcohol alone for patients under the age of 21. This is about one third (33%) of all drug misuse/abuse ED visits.[6]

2 Worldwide, alcohol abuse leads to 1.8 million deaths annually.[5] Nationally, according to the Alcohol-Attributable Deaths Report 2001-2005, 79,646 U.S. citizens with medium and high average daily alcohol consumption die each year because of alcohol-related causes, including traffic collisions and cirrhosis of the liver.[7] Direct and indirect health and social costs of alcoholism to the nation are estimated to be $185 billion annually.[8]

Caffeine is currently the most widely used psychoactive substance in the world. In the United States, 80% to 90% of adults regularly

consume behaviorally active doses of caffeine. Although research has shown that caffeine can cause a compulsive pattern of use, the prevalence of caffeine dependence and its clinical significance are difficult to determine.

ALCOHOL

EPIDEMIOLOGY OF ALCOHOL USE

Slightly more than half of Americans aged 12 or older reported being current drinkers of alcohol according to the National Survey on Drug Use and Health 2008 survey (51.6%).[4] This translates to an estimated 129 million people, which is similar to the 2007 estimate of 126.8 million people (51.1%). More than one fifth (23.3%) of persons aged 12 or older participated in binge drinking, defined as having five or more drinks on the same occasion, at least once in the 30 days prior to the survey.[4] This translates to about 58.1 million people. The rate in 2008 is the same as the rate in 2007 (23.3%). In 2008, heavy drinking was reported by 6.9% of the population aged 12 or older, meaning that they drank five or more drinks on the same occasion on at least five different days in the past month.[4]

THE DISEASE MODEL OF ADDICTION AS APPLIED TO ALCOHOLISM

The disease concept of addiction, using alcoholism as a model, states that addiction is a disease, and that individuals who suffer from the disease do not choose to contract the disease any more than someone who suffers from heart disease or diabetes mellitus chooses to contract that illness. A *disease* is defined as "any deviation from or interruption of the normal structure or function of any part, organ, or system (or combination thereof) of the body that is manifested by a characteristic set of symptoms and signs and whose etiology, pathology, and prognosis may be known or unknown."[9] Alcoholism, which is discussed as a prototype, meets all the definitional criteria. Diagnostic criteria for alcoholism do not specify frequency of drinking or amount of alcohol consumed. The key determinant is whether drinking is compulsive, out of control, and consequential when one drinks.

3 It has long been recognized that alcoholism is heritable, as 50% to 60% of first-degree relatives of alcoholics become alcohol dependent themselves.[10] Past discussions have focused on whether this heritable risk is because of genetics, environment, or both. Recent research has identified several traits (or phenotypes), that attenuate one's risk of alcohol dependence. Initially based on data from preclinical studies, pharmacogenomics studies have identified genotypic and functional phenotypic variants that either serve to protect patients or predispose them toward alcohol dependence.[11] Large-scale pharmacoepidemiologic studies have further elucidated the environmental risk factors that are associated with either protective effects or predisposition toward alcoholism.[12] This is referred to as the "genome x" environment interaction effect. The known susceptibility genes, phenotypic characteristics, and environmental risk factors are summarized in Table 75–1.[11–15]

TABLE 75-1 Genotypic, Phenotypic, and Environmental Factors That Increase Alcohol Dependence Risk

Susceptibility Genes	Phenotype	Environment
Regions on chromosomes 1 and 4 that code for the following receptors:	Personality traits that include:	Religious background
$GABA_A$	Novelty seeking	Urban residence (vs. rural)
Serotonin 1b	Impulsivity	History of sexual abuse
DRD4	Aggression	Being single
Tryptophan hydroxylase	Depression	Having deceased parents
Neuropeptide Y	Maximum number of alcoholic drinks consumed per day	
Gene that codes for:		
ALDH2		
5HTTLPR		

ALDH2, aldehyde dehydrogenase 2; DRD4, type 4 dopamine receptor gene; GABA, gamma aminobutyric acid; 5HTTLPR, 5 hydroxytryptamine transporter.

Data from Bierut et al.,[11] Heath et al.,[12] Luo et al.,[13] Boothby and Doering,[14] and Krystal et al.[15]

PHARMACOLOGY AND PHARMACOKINETICS OF ALCOHOL

Alcohol as a Drug

4 Alcohol is a central nervous system (CNS) depressant that affects the CNS in a dose-dependent fashion, producing sedation that progresses to sleep, unconsciousness, coma, surgical anesthesia, and finally fatal respiratory depression and cardiovascular collapse. Alcohol affects endogenous opiates and several neurotransmitter systems in the brain, including γ-aminobutyric acid (GABA), glutamine, and dopamine. Alcohol is available in a variety of concentrations in various alcoholic beverages. There are approximately 14 g of alcohol in a 12-oz (355 mL) can of beer (approximately 5%), 4 oz (118 mL) of nonfortified wine (approximately 10%–14%), or one shot (1.5 oz [44 mL]) of 80-proof whiskey (40%). Full consumption of this amount will cause an increase in blood alcohol level of approximately 20 to 25 mg/dL (4.3 to 5.4 mmol/L) in a healthy 70-kg (154 lb) male, although this varies with the time frame over which the alcohol is consumed, the type of alcoholic beverage, whether food is consumed along with it, and many patient variables. The lethal dose of alcohol in humans is variable, but deaths generally occur when blood alcohol levels are greater than 400 to 500 mg/dL (87 to 109 mmol/L).[16]

CLINICAL CONTROVERSY

Moderate alcohol consumption has been suggested to improve health. The definition of moderate consumption is narrow: one drink or less per day for females, and two drinks or less per day for males. The major limitations of this research thus far are the observational study designs that cannot demonstrate cause and effect relationsips between alcohol consumption and positive health benefits.[18–21] Additional potential confounders in these studies include diet, exercise, disease states, other drug therapies known to promote or hinder cardiovascular health, and psychosocial factors such as stress management.

Pharmacokinetics

Absorption of alcohol begins in the stomach within 5 to 10 minutes of oral ingestion. The onset of clinical effects follows fairly rapidly. Peak serum concentrations of alcohol usually are achieved 30 to 90 minutes after finishing the last drink, although it is variable depending on the type of alcoholic beverage consumed, what and when the person last ate, and other factors.[17]

More than 90% of alcohol in the plasma is metabolized in the liver by three enzyme systems that operate within the hepatocyte. The remainder is excreted by the lungs and in urine and sweat. Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase in the cell. In turn, acetaldehyde is metabolized to carbon dioxide and water by the enzyme aldehyde dehydrogenase. A second

TABLE 75-2 Specific Effects of Alcohol Related to BAC

BAC (%)[a] [mmol/L]	Effect
0.02–0.03 [4–8]	No loss of coordination, slight euphoria, and loss of shyness.
0.04–0.06 [9–14]	Feeling of well-being, relaxation, lower inhibitions, sensation of warmth. Euphoria. Some minor impairment of reasoning and memory, lowering of caution.
0.07–0.09 [15–21]	Slight impairment of balance, speech, vision, reaction time, and hearing. Euphoria. Judgment and self-control are reduced, and caution, reason, and memory are impaired. It is illegal to operate a motor vehicle in some states at this level.
0.10–0.125 [22–27]	Significant impairment of motor coordination and loss of good judgment. Speech can be slurred; balance, vision, reaction time, and hearing impaired. Euphoria. It is illegal to operate a motor vehicle at this level of intoxication.
0.13–0.15 [28–34]	Gross motor impairment and lack of physical control. Blurred vision and major loss of balance. Euphoria is reduced, and dysphoria is beginning to appear.
0.16–0.20 [35–43]	Dysphoria (anxiety, restlessness) predominates, nausea can appear. The drinker has the appearance of a "sloppy drunk."
0.25 [54]	Needs assistance in walking; total mental confusion. Dysphoria with nausea and some vomiting.
0.30 [65]	Loss of consciousness.
≥0.40 [>87]	Onset of coma, possible death caused by respiratory arrest.

BAC, blood alcohol concentration.
[a]Grams of ethyl alcohol per 100 mL of whole blood.

pathway for oxidation of alcohol uses catalase, an enzyme located in the peroxisomes and microsomes. The third enzyme system, the microsomal alcohol oxidase system, has a role in the oxidation of alcohol to acetaldehyde. These last two mechanisms are of lesser importance than the alcohol dehydrogenase–aldehyde dehydrogenase system.[17]

5 The metabolism of alcohol generally is said to follow zero-order pharmacokinetics.[17] This can, in fact, be an oversimplification because at very high or very low concentrations of alcohol the metabolism can follow first-order pharmacokinetics.[18] On average, the blood alcohol concentration (BAC) is lowered from 15 to 22.2 mg/dL (3.3 to 4.8 mmol/L) per hour in the nontolerant individual, assuming that the individual is in the postabsorptive state (Table 75–2). Alcohol has a volume of distribution of 0.6 to 0.8 L/kg, representing the total body water.[17]

CLINICAL INDICATORS OF CHRONIC ALCOHOL ABUSE

The CAGE questionnaire is a tool for detecting individuals more likely to be abusing alcohol and therefore at greater risk for alcohol withdrawal. CAGE is a mnemonic for four questions: (1) Do you ever feel the need to *c*ut down on your alcohol use? (2) Have you ever been *a*nnoyed by others telling you that you drink too much? (3) Have you ever felt *g*uilty about your drinking or something you did while drinking? (4) Do you ever have an "*e*ye opener"? A positive response to two or more of these four questions suggests an increased likelihood of alcohol abuse with an average sensitivity of 0.71 (71%) and an average specificity of 0.90 (90%).[19]

Acute Effects of Alcohol

At lower serum concentrations, euphoria and disinhibition may be noted. Slurred speech, altered perception of the environment, impaired judgment, ataxia, incoordination, nystagmus, and hyperreflexia may occur. As plasma levels increase combative and destructive behavior may occur. With higher levels still, somnolence and respiratory depression may ensue. The typical effects of various BACs are shown in Table 75–2, although effects vary from individual to individual.

Alcohol Poisoning

Acute alcohol poisoning usually occurs with rapid consumption of large quantities of alcoholic beverages, because this type of drinking delivers a bolus of alcohol to the gastrointestinal (GI) tract. With sustained drinking of moderate amounts of alcohol, the user passes out before a toxic dose of alcohol can be ingested, and/or the person vomits to rid the stomach of its toxic reservoir. With rapid drinking as described, the person may fall asleep or pass out without vomiting, allowing continued alcohol absorption from the GI tract, while the patient sleeps, until fatal BACs are achieved.

Laboratory Studies

In the emergency room, a BAC should be ordered in any patient in whom alcohol ingestion is suspected, regardless of the presenting complaint. For clinical purposes, most laboratories report BAC in units of mg/dL or mmol/L. In legal cases, results are reported in percentage (grams of ethyl alcohol per 100 mL of whole blood). If the diagnosis is unclear, if the intoxication seems atypical, or when there is suspicion of multiple drug ingestions, a complete toxicologic screen to rule out the presence of other substances may be useful.

CLINICAL PRESENTATION OF ALCOHOL INTOXICATION AND WITHDRAWAL

General

- Acute alcohol detoxification and withdrawal after chronic alcohol abuse is a serious condition that can require hospitalization and adjunctive pharmacotherapy. If the BAC gets high enough, death is possible.

Symptoms

- The intoxicated patient can present with slurred speech and ataxia. The patient can be sedated or unconscious. As BACs decrease rapidly, nausea, vomiting, and hallucinations can ensue. Delirium and seizures are the most severe symptoms.

Signs

- The intoxicated patient can present with nystagmus.
- In withdrawal, the patient can present with tachycardia, diaphoresis, or hyperthermia.

Laboratory Tests

- In the emergency department, a BAC should be ordered when alcohol ingestion is suspected. Most laboratories report BAC in units of milligrams per deciliter. A whole blood alcohol level of 150 mg/dL (33 mmol/L) reported in the hospital corresponds to 0.15% BAC obtained by law enforcement.
- A complete toxicologic screen to rule out the presence of other substances can be useful.

Other Diagnostic Tests

- Differentiate acute alcohol intoxication from other medical illnesses (e.g., head trauma).
- Use computed tomography (CT) on any patient with focal neurologic findings, failure to improve, new-onset seizures, or mental status out of proportion to degree of intoxication.

TREATMENT

ALCOHOL-RELATED DISORDERS

Alcohol Withdrawal

Goals for alcohol-dependent persons trying to decrease or discontinue alcohol intake include: (1) the prevention and treatment of withdrawal symptoms (including seizures and delirium tremens) and medical or psychiatric complications, (2) long-term abstinence after detoxification, and (3) entry into ongoing medical and alcohol-dependence treatment.

PHARMACOLOGIC THERAPY

6 Symptom-triggered treatment with a benzodiazepine is the current standard of care in alcohol detoxification to manage and minimize symptoms and avoid progression to the more severe stages of withdrawal. A meta-analysis was performed to provide evidence-based recommendations on the pharmacologic management of alcohol withdrawal[20] and alcohol withdrawal delirium.[21] Trials comparing different benzodiazepines demonstrated that all appear similarly efficacious in reducing signs and symptoms of withdrawal.[20,21] Lorazepam is preferred by many clinicians because it can be administered intravenously, intramuscularly, or orally with predictable results. Another consideration in the choice of benzodiazepines is their potential for abuse during recovery. A Cochrane Review[22] of the effectiveness and safety of benzodiazepines in the treatment of alcohol withdrawal symptoms was published in 2005. According to this report: "the available data show that benzodiazepines are effective against alcohol withdrawal seizures when compared to placebo. However, there are no prominent differences between benzodiazepines and other drugs in success rates. Data on safety outcomes are sparse and fragmented. There is a need for larger, well-designed studies in this field."

Treatment Regimens

Symptom-Triggered Therapy With symptom-triggered therapy, medication is given only when the patient has symptoms. This approach results in treatment that is shorter, potentially avoiding over sedation and allowing the clinician to focus on specific therapy for alcohol dependence.[20,21] A typical regimen would include lorazepam 2 mg administered every hour as needed when a structured assessment scale—such as the Clinical Institute Withdrawal Assessment–Alcohol, Revised—indicates that symptoms are moderate to severe (Table 75–3).[23]

TABLE 75-3 Pharmacologic Agents Used in the Treatment of Alcohol Withdrawal

Drug	Dose per Day (Unless Otherwise Stated)	Indication	Monitoring	Duration of Dosing	Level of Evidence[a]
Multivitamin	1 tablet	Malnutrition	Diet	At least until eating a balanced diet at caloric goal	B3
Thiamine	50–100 mg	Deficiency	CBC, WBC, nystagmus	Empiric × 5 days. More if evidence of deficiency	B2
Crystalloid fluids (typically D5-0.45 NS with 20 mEq of KCl per liter)	50–100 mL/hr	Dehydration	Weight, electrolytes, urine output, nystagmus if dextrose	Until intake and outputs stabilize and oral intake is adequate	A3
Clonidine oral	0.05–0.3 mg	Autonomic tone rebound and hyperactivity	Shaking, tremor, sweating, blood pressure	3 days or less	B2
Clonidine transdermal	TTS-1 to TTS-3	Autonomic tone rebound and hyperactivity	Shaking, tremor, sweating, blood pressure	1 week or less. One patch only	B3
Labetalol	20 mg IV every 2 hours as needed	Hypertensive urgencies and above	Blood pressure target	Individual doses as needed	B3
Antipsychotics, haloperidol	2.5 mg to 5 mg every four hours	Agitation unresponsive to benzodiazepines, hallucinations (tactile, visual, auditory, or otherwise) or delusions	Subjective response plus rating scale (CIWA-Ar or equivalent)	Individual doses as needed	B1
Antipsychotics, atypical Quetiapine Aripiprazole	 25–200 mg 5–15 mg	Agitation unresponsive to benzodiazepines, hallucinations, or delusions in patients intolerant of conventional antipsychotics	Subjective response plus rating scale (CIWA-Ar or equivalent)	Individual doses as needed in addition to scheduled antipsychotic	C3
Benzodiazepines Lorazepam Chlordiazepoxide Clonazepam Diazepam	 0.5–2 mg 5 mg–25 mg 0.5–2 mg 2.5–10 mg	Tremor, anxiety, diaphoresis, tachypnea, dysphoria, seizures	Subjective response plus rating scale (CIWA-Ar or equivalent)	Individual doses as needed Underdosing is more common than overdosing	A2
Alcohol oral		Prevent withdrawal	subjective signs of withdrawal	Wide variation	C3
Alcohol IV		Prevent withdrawal	subjective signs of withdrawal	Wide variation	C3

CBC, complete blood count; CIWA-Ar, Clinical Institute Withdrawal Assessment for Alcohol, revised; D5, dextrose 5%; KCl, potassium chloride; NS, normal saline; WBC, white blood cell count.

[a]Strength of recommendations, evidence to support recommendation: A, good; B, moderate; C, poor.

Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from Mayo-Smith,[20] Mayo-Smith et al.[21]

Fixed-Schedule Therapy Over the years, benzodiazepines given regularly at a fixed dosing interval have been used for alcohol withdrawal. The major problem with this approach is underdosing of the benzodiazepine because of the phenomenon of cross-tolerance (see Table 75–3). Current guidelines take exception with this rigid approach, urging clinicians to allow for some degree of individualization within fixed-schedule therapy.[20,21]

Treatment of Alcohol Withdrawal Seizures

Alcohol withdrawal seizures do not require treatment with an anticonvulsant drug unless they progress to status epilepticus because seizures usually end before diazepam or another drug can be administered.[21,23] Phenytoin, which is not cross-tolerant to alcohol, does not prevent or treat withdrawal seizures, and without an intravenous loading dose, therapeutic blood levels of phenytoin are not reached until acute withdrawal is complete. Patients experiencing seizures should be treated supportively. An increase in the dosage and slowing of the tapering schedule of the benzodiazepine used in detoxification or a single injection of a benzodiazepine can be necessary to prevent further seizure activity. Patients with a history of withdrawal seizures can be predicted to experience an especially severe withdrawal syndrome. In such patients, a higher initial dosage of a benzodiazepine and a slower tapering period of 7 to 10 days are advisable.

Treatment of Nutritional Deficits and Electrolyte Abnormalities

Fluid status should be carefully assessed, and fluid, electrolyte, and vitamin abnormalities should be corrected. Hydration can be necessary in patients with vomiting, diarrhea, increased body temperature, or severe agitation. Alcoholics often have electrolyte imbalances because of inadequate nutrition and fluid volume related to antidiuretic hormone inhibition. Hypokalemia can be corrected with oral potassium supplementation as long as renal function is adequate. Hypophosphatemia is common but should be allowed to gradually correct with adequate nutrition if phosphorus levels are greater than 1 mg/dL (0.32 mmol/L). Hypomagnesemia is also common, but routine magnesium replacement for alcohol withdrawal is not recommended. Thiamine (vitamin B_1) is often depleted in alcoholics, particularly those with poor nutrition. Thiamine supplementation is standard because it can prevent the development of the Wernicke-Korsakoff syndrome (e.g., mental confusion, eye movement disorders, and ataxia [poor motor coordination]), which may not be reversible once it develops. An initial dose of 100 mg IV or IM is commonly used. In practice, thiamine is usually given 100 mg once daily orally, intravenously, or intramuscularly for 3 to 5 days. It is not necessary for thiamine to be continued empirically for longer than 5 days (see Table 75–3).

Other nutritional deficits can also occur with chronic alcohol abuse primarily caused by poor eating habits. A multivitamin is usually given once daily. If clotting factors are abnormal because of decreased liver function and a relative inability to produce vitamin K–dependent clotting factors, then 2.5 to 25 mg of vitamin K can also be prescribed.

Alcohol hypoglycemia usually occurs in the absence of overt liver disease, and it is more likely if the patient is fasting or exercising or is sensitive to alcohol; it is less likely if the patient is obese. The alcohol directly interferes with hepatic gluconeogenesis but not glycogenolysis. The energy required for metabolism of alcohol is diverted away from the energy needed to take up lactate and pyruvate—substrates for gluconeogenesis. So, patients who drink alcohol can become hypoglycemic once glycogen stores are depleted. Neurologic symptoms of hypoglycemia can be confused with alcohol intoxication, and in the inpatient setting, blood glucose should be monitored regularly.

Treatment Settings

Alcohol withdrawal treatment can take place in hospitals, inpatient detoxification units, or outpatient settings. Inpatient treatment can be necessary when there are coexisting acute or chronic medical (including pregnancy), surgical, or psychiatric conditions that would complicate alcohol withdrawal. Only patients with mild to moderate symptoms should be considered for outpatient treatment, and it is a good idea to have a responsible, sober person available to help the patient monitor symptoms and administer medications. Patients with a strong craving for alcohol, those concurrently using other drugs, and those with a history of seizures or delirium tremens are not good candidates for outpatient treatment. Pharmacologic agents used in the treatment of alcohol withdrawal are summarized in Table 75–3.

PHARMACOLOGIC MANAGEMENT OF ALCOHOL DEPENDENCE

7 In the United States, disulfiram, naltrexone, the once-monthly injectable extended-release naltrexone, and acamprosate are the only four drugs that are FDA-approved for the treatment of alcohol dependence. Disulfiram acts as a deterrent to the resumption of drinking, and naltrexone is a competitive opioid antagonist that has been shown to reduce cravings for alcohol. Acamprosate is a GABA-ergic agonist that modulates alcohol cravings (Table 75–4). Other drugs, including nalmefene, bupropion, various serotonergic

TABLE 75-4 Pharmacologic Agents Used in the Treatment of Alcohol Dependence

Drug	Dosage Range per Day	Indication	Monitoring	Duration of Dosing	Level of Evidence[a]
Disulfiram	250 mg–500 mg	Deterrence	Facial flushing, liver enzymes	Indefinite	B2
Acamprosate	999 mg–1,998 mg and higher (333 mg tablets)	Craving	Patient-reported craving, renal function	Indefinite	A1
Naltrexone	50 mg–100 mg	Craving	Patient-reported craving	Indefinite	A1
Mood stabilizers (e.g., lamotrigine, topiramate, carbamazepine, valproic acid)	Seizure disorder doses	Craving	Patient-reported craving, plasma drug levels	Indefinite	B2
Antidepressants (e.g., clomipramine, bupropion, doxepin, maprotiline, fluoxetine)	Depression doses	Craving, depression, anxiety	Patient-reported craving	Indefinite	B2

[a]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively.
Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial. 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments. 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.
Data from Boothby and Doering,[14] Garbutt et al.[25,26]

agents (including selective serotonin reuptake inhibitors and vascular serotonin 5-HT_3 receptor antagonists), topiramate, and lithium also have been used either abroad or in the United States off-label for alcohol dependence. A recent meta-analysis[24] has been published with the primary objective of completing the efficacy profiles for acamprosate and naltrexone by contacting researchers when outcomes were missing and to compare them with each other. Naltrexone was found to have a significant effect on the maintenance of abstinence as well as the prevention of heavy drinking. Acamprosate was shown only to support abstinence; it did not influence alcohol consumption after the first drink. When the efficacy profiles of the two drugs were compared, acamprosate was found to be more effective in preventing a lapse, whereas naltrexone was better in preventing a lapse from becoming a relapse.

CLINICAL CONTROVERSY

The most difficult clinical problem in the treatment of alcohol-related illness is helping patients remain abstinent after alcohol detoxification. Acamprosate and naltrexone have been shown to be superior to nonpharmacologic therapy alone for maintenance of abstinence from alcohol; however, relapse during naltrexone and acamprosate therapy is still common. Disulfiram use has fallen out of favor. Studies have failed to prove it effective, and it is poorly tolerated. For this reason, most clinicians rarely recommend the use of disulfiram.

DISULFIRAM

Disulfiram deters a patient from drinking by producing an aversive reaction if the patient drinks. In the absence of alcohol, disulfiram has minimal effects. Disulfiram inhibits the liver enzyme aldehyde dehydrogenase in the biochemical pathway for alcohol metabolism, allowing acetaldehyde to accumulate. The resulting increase in acetaldehyde causes severe facial flushing, throbbing headache, nausea and vomiting, chest pain, palpitations, tachycardia, weakness, dizziness, blurred vision, confusion, and hypotension. Severe reactions including myocardial infarction, congestive heart failure, cardiac arrhythmia, respiratory depression, convulsions, and death can occur, particularly in vulnerable individuals. A recent review summarizes disulfiram's overall usefulness.[25]

NALTREXONE

Naltrexone, an opiate antagonist available in the United States since 1984 for the treatment of opioid dependence blocks the effects of exogenous opioids. In 1994, the FDA approved its use in the treatment of alcohol dependence. Naltrexone is thought to attenuate the reinforcing effects of alcohol, and those who consume alcohol while taking naltrexone report feeling less intoxicated and having less craving for alcohol.[25]

Short-term treatment (up to 12 weeks) with naltrexone decreases the chance of alcohol relapse by 36% versus placebo.[25] Naltrexone should not be given to patients currently dependent on opiates because it can precipitate a severe withdrawal syndrome. Naltrexone is associated with dose-related hepatotoxicity, but this generally occurs at doses higher than those recommended for treatment of alcohol dependence. Nevertheless, it is considered contraindicated in patients with hepatitis or liver failure, and liver function tests should be monitored monthly for the first 3 months and every 3 months thereafter.

Nausea is the most common side effect of naltrexone, occurring in approximately 10% of patients. Other side effects are headache, dizziness, nervousness, fatigue, insomnia, vomiting, anxiety, and somnolence. If dosed daily, naltrexone 50 mg per day is sufficient to effectively block μ-opioid receptors.

In April 2006, the FDA approved Vivitrol, a once-monthly intramuscular naltrexone formulation. The usual effective dose is 380 mg IM each month.[25,26] Extended release formulations reduce the likelihood of forgetting or choosing not to take medication, assuring that once the patient receives an injection, he or she will be "adherent" for the next month.[26]

ACAMPROSATE

Acamprosate is a glutamate modulator at the *N*-methyl-D-aspartate (NMDA) receptor that reduces alcohol craving. Acamprosate, approved in the United States in 2004, had been available in Europe for many years. Patients treated with acamprosate are more successful in maintaining abstinence from alcohol versus placebo. In addition, the combination of acamprosate and naltrexone has been shown to be more efficacious than acamprosate alone for the maintenance of abstinence from alcohol, when combined with psychosocial interventions. Acamprosate is well tolerated, with gastrointestinal adverse effects most common.[27] See Table 75–4 for dosing information for this and the other options used in treating alcohol dependence.

NICOTINE

Cigarette smoking is an enormous national health problem, and as healthcare professionals, we all must continue to work to help people to quit smoking. Clinical guidelines for tobacco use and dependence were released in 2000, which stressed the importance of healthcare professionals screening each patient for tobacco use.[28] In 2008, the clinical guidelines were updated, and many more patients are now counseled on the importance of smoking cessation. Telephone quit lines are now available in every state, and more patients are referred to smoking cessation counseling services. Additionally, more patients have access to FDA-approved medications for smoking cessation through private insurance or Medicaid compared to a decade ago.[28]

Despite this encouraging news, cigarette smoking continues to be the leading cause of preventable morbidity and mortality in the United States. When the CDC analyzed the data from the 2008 National Health Interview Survey (NHIS) it was found that the number of current smokers from the years 1998 to 2008 did decrease by 3.5%, but the proportion of current smokers from 2007 to 2008 did not change.[29] All healthcare providers should screen patients and utilize the clinical guidelines for tobacco use and dependence once a smoker is identified.[28]

EPIDEMIOLOGY OF TOBACCO USE

The National Survey on Drug Use and Health reported in 2007 that an estimated 28.6% (70.9 million) of the U.S. population 12 years of age and older used a tobacco product at least once in the month prior to being interviewed. Each day, about 1,000 persons younger than 18 years of age become regular smokers, and it is now estimated 20% (43.8 million) of high school students currently smoke on a regular basis.[30] In addition, 60 million Americans were current cigarette smokers, 13.3 million smoked cigars, 8.1 million used smokeless tobacco, and 2 million smoked pipes.[30] Data trends from the 2008 NHIS showed smoking prevalence did vary based on the level of education one had completed. The highest percentage of adults who admitted to smoking were adults who had earned a General Education Development certificate (41.3%). Those with a graduate level of education reported the lowest percentage of smoking (5.7%).[29]

The NHIS survey also found that 31.5% of adults currently living under the federal poverty level were current smokers in comparison with the 19.6% of smokers living above the federal poverty level.[29]

ECONOMIC IMPACT OF SMOKING

The direct healthcare expenditures associated with smoking total more than $96 billion per year, and the costs associated with lost productivity are estimated to be $97 billion. Smoking-attributable medical expenditures[31] in the adult Medicaid population total $22 billion, which is estimated as 11% of Medicaid program expenditures.[32] It has been calculated that if all Medicaid patients stopped smoking, the annual savings would reach $9.7 billion after 5 years.[28]

HEALTH RISKS OF SMOKING

Cigarette smoking substantially increases the risk of (1) cardiovascular diseases such as stroke, sudden death, and heart attack; (2) nonmalignant respiratory diseases including emphysema, asthma, chronic bronchitis, and chronic obstructive pulmonary disease; (3) lung cancer; and (4) other cancers.[33]

Exposure to environmental tobacco smoke (*passive exposure*) has been cited as the cause of 3,400 lung cancer deaths and 46,000 heart disease-related deaths in the United States every year.[34] Children who are exposed to environmental smoke have a higher risk of respiratory infection, asthma, and middle ear infections than those who are not exposed. Sudden infant death syndrome occurs more often in infants whose mothers smoked during pregnancy than in offspring of nonsmoking mothers.[34] The harmful effects of smoking on reproduction and pregnancy include reduced fertility and fetal growth, as well as increased risk of ectopic pregnancy and spontaneous abortion.[34]

PHARMACOLOGY OF NICOTINE

Nicotine is a ganglionic cholinergic agonist with pharmacologic effects that are highly dependent on dose. These effects include central and peripheral nervous system stimulation and depression, respiratory stimulation, skeletal muscle relaxation, catecholamine release by the adrenal medulla, peripheral vasoconstriction, and increased blood pressure, heart rate, cardiac output, and oxygen consumption. Cigarette smoking or low doses of nicotine produce an increased alertness and increased cognitive functioning by stimulating the cerebral cortex. At higher doses, nicotine stimulates the "reward" center in the limbic system of the brain.[35]

When nicotine is ingested a feeling of pleasure and relaxation can occur. Repetitive exposure to nicotine leads to neuroadaptation which builds tolerance to the initial effects. An accumulation of nicotine in the body leads to a more substantial withdrawal reaction if cessation is attempted.[36] Common symptoms experienced during withdrawal can include anxiety, difficulties concentrating, irritability, and strong cravings for tobacco. Onset of these withdrawal symptoms usually occurs within 24 hours and can last for days, weeks, or longer.[36]

CLINICAL PRESENTATION OF NICOTINE WITHDRAWAL

General

- The patient may experience anxiety but may not be in acute distress. Symptoms can wax and wane over time.

Symptoms

- The patient may complain of cravings, difficulty concentrating, frustration, irritability, and impatience. Hostility, insomnia, and restlessness can also occur.

Signs

- Increased skin temperature can be present.

TREATMENT

Nicotine Dependence

AGENCY FOR HEALTHCARE RESEARCH AND QUALITY CLINICAL PRACTICE GUIDELINE: TREATING TOBACCO USE AND DEPENDENCE

The Agency for Healthcare Research and Quality (AHRQ) periodically convenes expert panels to develop clinical guidelines for healthcare practitioners. Because of the widespread prevalence of smoking-related illnesses, its related morbidity and mortality, and the economic burden imposed, the agency convened a panel of experts in 1994 to develop guidelines on the treatment of tobacco addiction. The resultant guideline for smoking cessation was released in 1996. In May 2008, an updated version of the 1996 Smoking Cessation Clinical Practice Guideline was issued by AHRQ.[28]

The revised guideline suggests strategies for providing appropriate treatments for every patient. The panel reminds us that effective treatments for tobacco dependence now exist and that every patient should receive at least minimal treatment every time he or she visits a clinician (Figs. 75–1 and 75–2).

The guideline identified a number of key findings that clinicians should use:

1. Tobacco dependence is a chronic condition that often requires repeated intervention. However, effective treatments exist that can produce long-term or permanent abstinence.
2. Because effective tobacco dependence treatments are available, every patient who uses tobacco should be offered at least one of these treatments:
   - Patients willing to try to quit tobacco use should be provided with treatments that are identified as effective in the guideline.
   - Patients unwilling to try to quit tobacco use should be provided with a brief intervention that is designed to increase their motivation to quit.
3. It is essential that clinicians and healthcare delivery systems (including administrators, insurers, and purchasers) institutionalize the consistent identification, documentation, and treatment of every tobacco user who is seen in a healthcare setting.
4. Brief tobacco dependence treatment is effective, and every patient who uses tobacco should be offered at least brief treatment.
5. There is a strong dose-response relationship between the intensity of tobacco dependence counseling and its effectiveness. Treatments involving person-to-person contact (via individual, group, or proactive telephone counseling) are consistently effective, and their effectiveness increases with treatment intensity (e.g., minutes of contact).

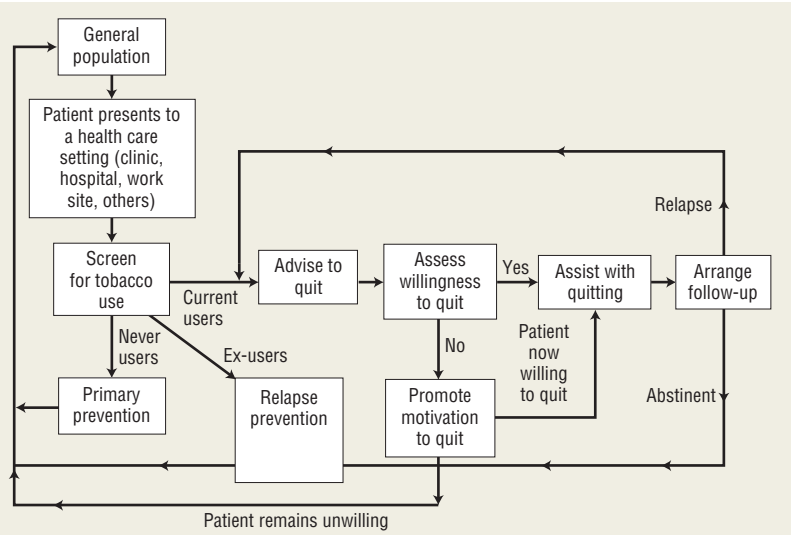

FIGURE 75-1. Model for treatment of tobacco use and dependence.

6. Three types of counseling and behavioral therapies were found to be especially effective and should be used with all patients who are attempting tobacco cessation:
   - Provision of practical counseling (problem-solving/skills training)
   - Provision of social support as part of treatment (intratreatment social support)
   - Help in securing social support outside treatment (extratreatment social support)

7 Numerous effective pharmacotherapy options for smoking cessation now exist (Table 75–5). Seven first-line pharmacotherapy options reliably increase long-term smoking abstinence rates: sustained-release (SR) bupropion, nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, nicotine patch, and varenicline. Combinations of these should be considered if a single agent has failed.

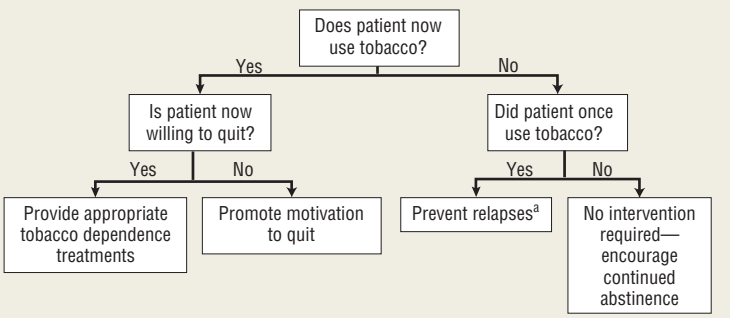
Two second-line pharmacotherapy options are considered efficacious and can be considered by clinicians if first-line options are not effective: clonidine and nortriptyline.

Tobacco-dependence treatments are both clinically effective and cost-effective relative to other medical and disease prevention interventions. As such, insurers and purchasers should ensure all insurance plans include as a reimbursed benefit the counseling and pharmacotherapeutic treatments that are identified as effective in this guideline, as well as clinician reimbursement for providing tobacco dependence treatment just as they are reimbursed for treating other chronic conditions.

OTHER FACTORS IMPORTANT TO THE SUCCESS OF A SMOKING-CESSATION STRATEGY

The AHRQ expert panel emphasized the importance of the type and intensity of the contact with the counselor to the success of the intervention. When interventions last for more than 10 minutes, the increase in cessation rates is much better than when interventions do not involve contact with a professional. Group and individual counseling is more effective than no intervention in increasing abstinence rates. Self-help materials (e.g., handouts, pamphlets, and brochures) without any direct physical contact are not effective.[37] Interventions are more successful when they include social support and training in general problem-solving skills, stress management, and relapse prevention. The number of treatment sessions offered is also important. Providing at least four or more sessions, longer than 10 minutes in length, and if possible providing treatments from multiple types of clinicians have proven higher success rates compared to less intensive interventions.[28] Although comprehensive behavioral interventions have been shown to be more effective in helping people quit smoking and remain abstinent, less intensive treatments are beneficial as well. Even minimal contacts lasting less than 3 minutes and simple advice to quit are more successful in increasing cessation rates than intervention involving no contact.[28]

8 Counseling alone can be effective, but counseling efficacy is further augmented by the addition of pharmacotherapy. In a meta-analysis which included 111 trials with more than 43,000 participants using one or more of the five forms of nicotine replacement therapy (NRT) including nicotine gum, nasal spray, patches,



[a]Relapse prevention interventions are not necessary in the case of the adult who has not used tobacco for many years.

FIGURE 75-2. Algorithm for treating tobacco use.

lozenges, or inhaler, it was found the use of NRT led to a significant rate of cessation compared to the cessation rates with placebo.[38]

Although comprehensive programs are most effective, few smokers (10%–15%) seek formal assistance in quitting.[28]

PHARMACOLOGIC THERAPY FOR SMOKING CESSATION

All patients attempting to quit should be encouraged to use effective pharmacotherapy agents for smoking cessation except in the presence of special circumstances. Long-term smoking-cessation pharmacotherapy should be considered as a strategy to reduce the likelihood of relapse. As with other chronic diseases, the most effective treatment of tobacco dependence encompasses multiple modalities. Pharmacotherapy is a vital element of a multicomponent smoking cessation program that should also always include nonpharmacologic components. The clinician should encourage all patients initiating a quit attempt to use one or a combination of efficacious pharmacotherapy agents, although pharmacotherapy use requires special consideration with some patient groups (e.g., those with medical contraindications, those smoking fewer than 10 cigarettes a day, pregnant or breast-feeding women, and adolescent smokers). The role of pharmacotherapy in smoking cessation is summarized in Table 75–5.

NICOTINE-REPLACEMENT THERAPY

A Systematic Review of Nicotine Replacement Therapy

In 2009, a systematic review[38] of published studies was performed to determine the effectiveness of the different forms of NRT (e.g., chewing gum, transdermal patches, nasal spray, inhalers, and tablets) in achieving abstinence from cigarettes or a sustained reduction in the amount smoked. The review was also designed to determine whether the effect is influenced by the clinical setting in which the smoker is recruited and treated, the dosage and form of the NRT used, or the intensity of additional advice and support offered to the smoker; to determine whether combinations of NRT are more effective than one type alone; and to determine its effectiveness compared to other pharmacotherapy agents.

The review was limited to randomized trials in which NRT was compared to placebo or no treatment, or where different doses of NRT were compared. The main outcome measure was abstinence from smoking after at least 6 months of follow-up. For each trial, researchers used the most rigorous definition of abstinence, and confirmation with biochemical markers where available. The review includes 132 studies, 111 of which included a placebo or non–nicotine control arm. All of the commercially available forms of NRT were effective for smoking cessation. Use of NRT doubled the odds of quitting. Higher doses of nicotine patch can produce additional small increases in quit rates compared to lower doses. Only one study directly compared NRT to another pharmacotherapy, in which bupropion was significantly more effective than nicotine patch or placebo.[38]

In late 2009, the first head-to-head placebo-controlled trial comparing five smoking cessation pharmacotherapies with 1,504 smokers who had smoked at least 10 cigarettes per day for 6 months and who were interested in achieving cessation was published. Patients were randomized to receive SR bupropion, nicotine patch, nicotine lozenge, nicotine patch plus nicotine lozenge, bupropion plus nicotine lozenge, or placebo. The patients were required to use the assigned NRT plus attend six 10 to 20 minute individual counseling sessions. Two of the counseling sessions were held prior to beginning NRT, the second on the actual quit date. The other counseling sessions were then scheduled on weeks 1, 2, 4, and 8 from the quit date. Abstinence was confirmed by using blood tests to determine

TABLE 75-5 Pharmacologic Agents Used for Smoking Cessation

Drug	Place in Therapy	Dosage Range	Duration	Comments/Monitoring Parameters	LOE[d]
Bupropion SR[a,b]	First-line	Titrate up to 150 mg orally twice daily.	3 to 6 months	Patients receiving both bupropion and a nicotine patch should be monitored for hypertension.	A1
Clonidine[b,c]	Second-line	Titrate to response; 0.2 to 0.75 mg per day	6 to 12 months	Monitor baseline electrolyte and lipid profiles, renal function, uric acid, complete blood count, and blood pressure	B2
Nicotine polacrilex (gum)[a]	First-line	Initial dose depends on smoking history: 2 to 4 mg every 1 to 8 hours	12 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy.	A1
Nicotine inhaler[a]	First-line	24 to 64 mg per day (total daily dose)	3 to 6 months (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy.	A1
Nicotine nasal spray[a]	First-line	8 to 40 mg per day (total daily dose)	14 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy.	A1
Nicotine patch[a]	First-line	Initial dose depends on smoking history: 7 to 21 mg topically once daily	6 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy.	A1
Nortriptyline[b,c]	Second-line	Titrate up to 75 to 100 mg orally daily	6 to 12 months	Dry mouth, blurred vision, and constipation are dose-dependent adverse effects.	B2
Varenicline[b]	First-line	Titrate up to 1 mg orally twice daily	3 to 6 months	Monitor renal function, especially in elderly patients. Nausea, headache, insomnia are dose-dependent adverse effects.	A1

LOE, level of evidence.

[a]Nicotine replacement therapies can be combined with each other and/or bupropion to increase long-term abstinence rates.

[b]Do not abruptly discontinue. Taper up initially, and taper off once therapy is complete.

[c]Clonidine and nortriptyline are not FDA-approved for smoking cessation.

[d]Strength of recommendations, evidence to support recommendation: A, good; B, moderate; C, poor.

Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from U.S. Department of Health and Human Services.[28,34]

carbon monoxide. At 6 months it was found the quit rates were 40.1% for the nicotine patch plus nicotine lozenge, 34.4% for the nicotine patch, 33.5% for the nicotine lozenge, 33.2% for bupropion plus nicotine lozenge, 31.8% for bupropion alone, and 22.2% for placebo. It was postulated that the nicotine patch provided a stable blood level of nicotine in the blood to aid with withdrawal but the addition of the nicotine lozenge allowed for coverage during intense craving periods to decrease the chances of relapse.[39]

The AHRQ guidelines recommend use of NRT in the forms of transdermal nicotine patches, nicotine gum, nicotine sprays, nicotine inhalers, and nicotine lozenges.[28] Although cardiovascular disease is not an independent risk factor for acute myocardial events in patients taking NRT, NRT should be used with caution among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post–myocardial infarction period, those with serious arrhythmias, and those with serious or worsening angina pectoris.[28]

Nicotine Gum

Clinicians should offer 4-mg rather than 2-mg nicotine gum to highly dependent smokers.[28] The 2-mg gum is recommended for patients smoking fewer than 25 cigarettes per day, whereas the 4-mg gum is recommended for patients smoking 25 or more cigarettes per day. Generally, the gum should be used for up to 12 weeks, no more than 24 pieces chewed per day. The dosage and duration of therapy should be tailored to meet the needs of each patient.

Nicotine gum currently is available exclusively as an over-the-counter medication and is packaged with important instructions on correct use, including chewing instructions. There is currently little evidence to suggest that combined use of the patch and gum increases abstinence beyond 24 weeks.

Gum should be chewed slowly until a peppery or minty taste emerges and then "parked" between cheek and gums to facilitate nicotine absorption through the oral mucosa. It should be chewed slowly and intermittently and parked for about 30 minutes or until the taste dissipates. Acidic beverages (e.g., coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during chewing. Patients often do not use enough gum to get the maximum benefit: they chew too few pieces per day, and they might not use the gum for a sufficient number of weeks. Instructions to chew the gum on a fixed schedule (at least one piece every 1–2 hours) for at least 1 to 3 months can be more beneficial than ad libitum use.

Nicotine Patch

9 The nicotine patch is available both as an over-the-counter medication and as a prescription drug and it approximately doubles long-term abstinence rates over those produced by placebo interventions.[38] Treatment of 8 weeks or less has been shown to be as efficacious as longer treatment periods. The 16- and 24-hour patches are of comparable efficacy.[33] Clinicians should consider starting treatment on a lower patch dose in patients smoking 10 or fewer cigarettes per day.[28]

A patch should be applied as soon as the patient wakes on the quit day and at the start of each day thereafter. The patient should place a new patch on a relatively hairless location, typically between the neck and waist. There are no restrictions on activity while using the patch. Patients who experience sleep disruption should remove the 24-hour patch prior to bedtime or use the 16-hour patch.

Nicotine Nasal Spray

Nicotine nasal spray more than doubles long-term abstinence rates when compared with a placebo spray. Nicotine nasal spray is available exclusively as a prescription medication. A dose of nicotine nasal spray consists of one 0.5-mg delivery to each nostril (1 mg total). Initial dosing should be one to two doses per hour, increasing as needed for symptom relief. The minimum recommended treatment is 8 doses per day, with a maximum limit of 40 doses per day (5 doses per hour). Each bottle contains approximately 100 doses. Recommended duration of therapy is 3 to 6 months. Patients should not sniff, swallow, or inhale through the nose while administering doses because this increases irritating effects.

Nicotine Lozenge

The nicotine lozenge is available as a 2-mg and a 4-mg dose. The 2-mg lozenge is recommended for patients who normally smoke their first cigarette later than 30 minutes after awakening, and the 4-mg lozenge is recommended for smokers who smoke within 30 minutes of waking. It is recommended that patients use at least nine lozenges daily the first 6 weeks of therapy. The duration of treatment is 12 weeks. It is recommended no more than 20 lozenges should be used in 1 day.[28] In comparison to the nicotine gum, nicotine release is more controlled and does not depend on the correct "chew and park" method required by the gum. The most common side effect of the lozenge is nausea. As with the nicotine gum, acidic beverages (e.g., coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during use of the lozenge.[28]

Instructing Patients in the Use of NRT

Compliance with NRT improves when the patient is presented a clear rationale for its use and a realistic expectation about the response. It should be explained to the patient that nicotine is responsible for addiction and that discontinuation of the nicotine causes craving for cigarettes, tension, irritability, sadness, problems with sleep, and difficulty concentrating. These are partly due to nicotine withdrawal. The patient should be told that using the patch results in less desire to smoke and provides an opportunity for a new nonsmoker to practice all the new nonsmoking skills without being burdened by craving. The patient should understand that with smoking, there are naturally peaks and valleys in the amount of nicotine in the bloodstream. With the patch there is a steady gradual rise in the blood nicotine concentration that levels off and remains constant for much of the day and then gradually decreases while the person is asleep. Maintaining an adequate blood level of nicotine lessens withdrawal symptoms.

A similar rationale can be used if patients are using gum. It should be emphasized that NRT is not a "magic bullet" and that the use of coping skills is essential for abstinence. The patch or the gum only buys time by reducing withdrawal symptoms and giving individuals a chance to figure out alternatives that they can use in place of smoking.[28]

CLINICAL CONTROVERSY

Some clinicians are hesitant to prescribe nicotine replacement therapy for smoking cessation during pregnancy because the safety and efficacy of nicotine replacement therapy has not been established in controlled clinical trials in this population. This logic is somewhat counterintuitive in that continued smoking exposes the unborn child to much higher levels of nicotine, and the harmful consequences of cigarette smoking during pregnancy are well documented.

Side Effects

Nicotine replacement products have relatively few side effects. Nausea and light-headedness are possible symptoms of nicotine overdose that warrant a reduction of the nicotine dose.

The most frequent side effect with the nicotine patch is skin irritation related to the adhesive or the medium containing nicotine and not to the nicotine itself. Approximately 50% of patients report skin irritation during the course of treatment with the patch. The patch site can be rotated to diminish this problem. The use of over-the-counter hydrocortisone cream (1%) or triamcinolone cream (0.5%) is recommended as a local treatment for patch-related skin irritations. Switching to a different brand of patch also can alleviate the problem because different products use different adhesives or media. The gum can be used instead of the patch when the skin irritation is severe. Less than 5% of patients were forced to discontinue therapy because of skin reactions.

Approximately 23% of patients using the patch report sleep disturbances, but the insomnia is hard to differentiate from the sleeplessness that often accompanies withdrawal itself, especially during the first few weeks of quitting.

Duration

Those who commit to quitting smoking using nicotine replacement should be told that treatment for up to three months is common.[40] However, some patients will experience severe withdrawal even beyond this time period so long term use of NRT might be indicated. Long term use of NRT has not been linked to any safety concerns and is supported by the 2008 updated U.S. Public Health Service Guidelines.[28]

Economic and Pharmacoeconomic Considerations

Most health insurers provide coverage for the chronic illnesses caused by smoking (e.g., chronic obstructive pulmonary disease, cancer, and myocardial infarction), yet few provide coverage for treating the nicotine addiction that caused those ailments.[28] The U.S. Public Health Service's Clinical Practice Guideline on Treating Tobacco Use and Dependence Update 2008 strongly encourages a comprehensive treatment plan for smoking cessation which includes both use of the recommended pharmacotherapy agents and extensive counseling. It has been shown if a comprehensive smoking cessation program is a paid or covered health benefit within the insurance plan an increased success rate for cessation is seen.[28] In 2006 it was estimated that 35% of Medicaid recipients smoked cigarettes but the current coverage of smoking cessation pharmacotherapy agents as well as counseling sessions are still very limited, and availability is inconsistent with the current federal clinical guidelines.[41] Accounting for direct healthcare expenditures and productivity losses (approximately $97 billion per year), the total economic burden of smoking is approximately $193 billion per year.[31] The CDC reports $203.9 billion was available to states from the years 2000 to 2009 from tobacco taxes and legal settlements. An investment of only 15% of these funds the states received on an annual basis would have funded every state tobacco control program. Unfortunately, it has been reported that states spent less than 3% on any tobacco prevention and cessation programs.[29] Expanding coverage of not only the pharmacotherapy agents available for smoking cessation but the reimbursement for counseling as recommended by the updated guidelines by the health insurers and by Medicaid programs is imperative to improve smoking abstinence rates.

NON-NICOTINE OPTIONS

Bupropion

⑩ Bupropion inhibits neuronal reuptake and potentiates the effects of norepinephrine and dopamine. Although its precise mechanism in smoking cessation is not well understood, dopamine has been associated with the rewarding effects of addictive substances. Withdrawal symptoms can be decreased by virtue of bupropion inhibition of norepinephrine uptake. The AHRQ panel concluded that SR bupropion is an efficacious smoking cessation treatment that patients should be encouraged to use.[28] Contraindications for bupropion use include current or past seizure disorders, a history of monoamine oxidase inhibitor use over the last 14 days, and a history of anorexia nervosa or bulimia. Along with multiple other precautions listed in the product labeling, current alcohol use, use of medications which lower seizure threshold (e.g., antidepressants, antipsychotics), and depression are possible concerns when using this medication.[28] In 2009, the FDA started requiring the manufacturers of Zyban (bupropion) and generic manufacturers to add new black box warnings and develop a medication guide highlighting the risk of serious neuropsychiatric symptoms in patients using this product. Possible symptoms include depressed mood, agitation, anxiety, hostility, changes in behavior, suicidal thoughts and behavior, and attempted suicide.[28]

A double-blind, placebo-controlled, randomized multicenter trial was conducted in which healthy smokers were randomized to receive either SR bupropion 150 mg twice daily or a placebo daily for 7 weeks and subsequently seen for counseling and follow-up for a total of 52 weeks. The primary end points were biochemically confirmed continuous abstinence at weeks 7 and 52. The authors specifically conducted this trial in the primary care setting to verify the general applicability of the results to the intended end users.[42] While similar studies have been performed in academic settings and have shown favorable results, the authors contend the real therapeutic potential or impact of a pharmacologic approach to smoking cessation must be evaluated by general practitioners in the primary care setting. They further assert that the approach should address healthy smokers and use continuous abstinence at week 52 as the most valid outcome measure. The results of this study showed bupropion was efficacious, with an absolute 25% of participants continuously abstinent at 1 year; it doubled the odds of continuous abstinence from week 4 to week 7 and from week 4 to week 52 compared with placebo.

A recent meta-analysis was conducted by the Cochrane Collaboration involving 49 trials utilizing bupropion for smoking cessation. Bupropion was shown to significantly increase the incidence of long-term cessation when used as a sole agent in 36 separate trials. Other trials which used bupropion as an add-on agent with NRT did not show additional benefit for improving cessation rates. The incidence of seizures was fairly low when considering 8,000 people were exposed to bupropion in these multiple studies and the rate of seizures was still less than the 1:10,000 estimated risk listed in the product safety information.[43]

⑩ For smoking cessation, the manufacturer recommends a dosage of 150 mg once daily for 3 days and then twice daily for 7 to 12 weeks or longer, with or without NRT. Patients are instructed to stop smoking during the second week of treatment and are encouraged to use counseling and support services along with the medication. For maintenance therapy, consider SR bupropion 150 mg twice daily for up to 6 months.[28]

Varenicline (Chantix)

⑪ Varenicline, a new and novel aid to smoking cessation, was approved by the FDA in 2006. It acts at sites in the nicotine-affected brain in two ways: by providing nicotine effects to ease withdrawal

symptoms and by blocking the effects of nicotine from cigarettes if they resume smoking. Specifically, varenicline is a partial agonist that binds selectively to α_4-β_2-nicotinic acetylcholine receptors with a greater affinity than nicotine. When bound to the receptor, the drug blocks nicotine from binding and also evokes a response but to a lesser degree than nicotine. The stimulation of the receptor results in release of dopamine and thus provides a type of "reward" that can decrease craving and withdrawal symptoms.[44]

The recommended dosage for varenicline is 0.5 mg daily for 3 days, increase to 0.5 mg twice daily for 3 days, and then increase to 1 mg twice daily for a standard 12-week treatment. If abstinence has not been achieved after the 12-week treatment, then a second 12-week treatment may be prescribed.[44]

Varenicline is listed as a first-line agent in the updated clinical guidelines on treating tobacco use and dependence. Seven trials comparing varenicline with placebo, three of which also had a comparison with bupropion, were reviewed in a recent Cochrane Review meta-analysis. Varenicline caused a two- to three-fold increased likelihood of long-term smoking cessation compared with placebo. It was also found that varenicline's rate of cessation was greater than that of bupropion.[45]

Since 2006, when varenicline was approved by the FDA, alarming numbers of adverse effects including suicidal thoughts, erratic behavior, and aggressive behavior have been reported. The large number of reports led to the release of a Public Health Advisory by the FDA in February 2008.[46] The advisory stressed the importance of screening for any type of psychiatric illness or any behavior changes after starting varenicline. A boxed warning along with an update of the medication guide from the manufacturer was required by the FDA.[46] Specific warnings stress that patients should report any history of psychiatric illness and any changes in behavior or mood immediately to their prescribing practitioner. Impairment of the ability to drive or operate heavy machinery and the possibility of strange or vivid dreams are also stressed in the medication guide.[46]

SECOND-LINE MEDICATIONS

Second-line medications are pharmacotherapies for which there is evidence of efficacy for treating tobacco dependence, but which have a more limited role than first-line medications because (1) the FDA has not approved them for a tobacco-dependence treatment indication, and (2) there are more concerns about potential side effects than exist with first-line medications.[28] Second-line treatments should be considered for use on a case-by-case basis after first-line treatments have been used or considered.

Clonidine

Clonidine has been found to be efficacious as a smoking cessation treatment, although its only labeled indication is for treatment for hypertension. It can be used off-label as a second-line agent to treat tobacco dependence. A recent meta-analysis of six trials showed that clonidine increased smoking cessation rates by 11% (odds ratio [OR], 1.89; confidence interval [CI], 1.30–2.14). There was a high incidence of dose-dependent side effects, particularly dry mouth and sedation.[47] It should be noted that abrupt discontinuation of clonidine can result in symptoms such as nervousness, agitation, headache, and tremor, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine levels.

Doses used in various clinical cessation trials have varied significantly, from 0.15 to 0.75 mg/day orally to 0.1 to 0.2 mg/day transdermally, without a clear dose-response relation to cessation. Initial dosing typically is 0.1 mg orally twice daily or 0.1 mg/day transdermally, increasing by 0.1 mg/day each week if needed. The duration also varied across the clinical trials, ranging from 3 weeks to 12 months. Most commonly reported side effects include dry mouth, drowsiness, dizziness, sedation, and constipation. Clonidine will lower blood pressure in most patients, thus blood pressure should be monitored.[28]

Nortriptyline

Nortriptyline is also considered to be efficacious as a second-line agent to treat tobacco dependence. It should be considered for smoking cessation under a clinician's direction in patients unable to use first-line medications because of contraindications and in patients who failed using first-line medications. Therapy is initiated 10 to 28 days before the quit date to allow nortriptyline to reach steady state at the target dose. Smoking cessation trials have initiated treatment at a dose of 25 mg/day, increasing gradually to a target dose of 75 to 100 mg/day. Duration of treatment used in smoking cessation trials has been approximately 12 weeks. Most commonly reported side effects include sedation, dry mouth, blurred vision, urinary retention, light-headedness, and tremor.[28]

Future Treatments

Work continues on the development of vaccines to be used in treating nicotine addiction. NicVAX (an experimental nicotine conjugate vaccine) is designed to cause the immune system to produce antibodies that bind to nicotine and prevent it from entering the brain. As a result, the positive stimulus in the brain that is normally caused by nicotine is no longer present, thereby taking away the physical motivation for smoking, consequently helping people to quit.[48,49]

Results from the phase II clinical studies on 301 patients who were smoking an average of 24 cigarettes a day showed the vaccine "induced the production of a long lasting antibody which helped in the prevention of a smoking relapse for up to 2 months in approximately 25% of the study participants."[50]

CLINICAL PRESENTATION OF EXCESSIVE CAFFEINE INTAKE

General

- The patient may not be in acute distress.

Symptoms

- The patient may complain of nausea, vomiting, diarrhea, and psychomotor agitation, and can appear restless, nervous, and excited.

Signs

- The patient can present with facial flushing, diuresis, and muscle twitching.
- Tachycardia or cardiac arrhythmias can also occur

Laboratory Tests

- Caffeine serum concentrations are rarely used clinically.

CAFFEINE

Caffeine is the most widely consumed behaviorally active substance in the world, generating an increased sense of well-being, happiness, energy, alertness, and sociability.[51] Caffeinism is the term coined to describe the clinical syndrome produced by acute or chronic overuse of caffeine. The syndrome usually is characterized by CNS and peripheral manifestations, most notably anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiologic complaints.[52]

As many as one in five adults consume doses of caffeine generally considered large enough to cause clinical symptoms.[51,52]

Pharmacologically, the risk of developing some meaningful clinical manifestations becomes high when intake exceeds 500 mg/day. This places 20% to 30% of North Americans at risk.[51] Caffeine has been proposed as a "model of drug abuse" despite the facts that its sale is largely unrestricted and that heavy consumption of caffeine-containing beverages is not considered to be drug abuse. An exhaustive review of caffeine dependence focused on the potential for abuse of caffeine and the nature of tolerance and withdrawal.[51] The information below represents a broad overview of these topics, and the reader interested in more detail is urged to consult the review by Juliano and Griffiths.[51]

EPIDEMIOLOGY OF CAFFEINE USE AND ABUSE

Caffeine is used by 80% of the population of the United States. In 1999 there were 108,000,000 coffee consumers in the United States spending approximately $9.2 billion in the retail sector and $8.7 billion in the food service sector every year.[53] The National Coffee Association found in 2001 that 52% of the adult population of the United States drinks coffee daily.[54] Newer market research data are available but are a closely protected proprietary secret. It is safe to say that in the 10 years since these data were freely available, coffee consumption has likely increased.

The majority of caffeine users progress to a pattern of frequent or daily consumption. Approximately one-fourth eventually begin consuming large quantities, exceeding 500 mg/day, and conservatively, 10% of all adults then progress to develop the syndrome of caffeinism. Mean daily consumption of caffeine in American children is surprisingly high. The Framingham Children's Study[57] investigated the amounts of caffeine consumed each day by children between the ages of 6 and 10 years (mean, 8.4 years for boys and 8.1 years for girls). Mean intake of caffeine was 16 ± 9.6 mg/day. Caffeinated soft drinks and chocolate furnished almost all of the caffeine.[55]

ENERGY DRINKS

In recent years a number of energy drinks containing caffeine, taurine, vitamins, and usually sugar have found their way onto the American market. Sold under brand names such as Red Bull, Monster Energy, Rockstar, and Full Throttle, these products are especially popular with adolescents and emerging adults, with sales exceeding half a million dollars in 2006.[56] This represents a more than 50% increase over 2005.[56] These products are generally marketed to enhance alertness or providing a short-term energy boost and do not constitute suitable sources of rehydration or restoration of electrolytes in association with athletic activity.[56]

Additionally, several manufacturers have marketed alcoholic beverages that have caffeine as an additional ingredient. Some may have other stimulant ingredients such as guarana, taurine, and ginseng. The Center for Science in the Public Interest has chosen to call these beverages "alcospeed."[57]

DIFFERENTIAL DIAGNOSIS

Caffeine intoxication is the only official diagnosis associated with caffeinism in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*.[9] Caffeine-induced anxiety can manifest as restlessness, nervousness, excitement, insomnia, diuresis, flushing, GI disturbance, muscle twitching, irritability, and jitteriness. If caffeine-induced insomnia requires specific treatment, caffeine-induced sleep disorder is an appropriate *DSM-IV-TR* diagnosis.[9]

Because excessive caffeine consumption is so widespread, a thorough history of caffeine use should be included in the routine assessment of all new patients in primary care medical settings. In this manner, the practitioner can use the information gathered to uncover high levels of caffeine intake and then use the information to pinpoint the cause of clinical signs and symptoms typical of caffeinism. Clinical manifestations of caffeinism almost always will lessen in intensity or disappear completely within 1 to 2 weeks after removing the drug.

PHARMACOLOGY OF CAFFEINE

Caffeine is rapidly and completely absorbed from the GI tract, reaching a peak blood level within 30 to 45 minutes of oral ingestion. It easily crosses the blood–brain barrier, and levels achieved in the brain are proportional to the dose administered.

The half-life of caffeine in humans is approximately 3.5 to 5 hours. Serious problems rarely result from overdoses of caffeine. In fact, the amount of caffeine needed to cause death in an average adult male is 5 to 10 g, the equivalent of 50 to 100 cups of regular brewed coffee. Thus the risk of overdose from dietary sources of caffeine is virtually nonexistent.

Caffeine increases the heart rate and force of contraction. It also has a strong diuretic effect. The key factor promoting caffeine use and dosage increases can be the drug's reinforcing effect on pleasure and reward centers of the brain. Caffeine's pharmacologic actions appear comparable (although less potent) in some aspects with those of other stimulants, such as amphetamines and cocaine.

CAFFEINE DEPENDENCE

Research has shown that abstinence from caffeine induces a distinct withdrawal syndrome. Evidence for the existence of a caffeine dependence syndrome was presented by Strain and associates.[58] In a structured psychiatric interview, subjects self-identified as having problems with caffeine use were evaluated for features of a *DSM-IV-TR* diagnosis of drug dependence. Those judged as caffeine dependent manifested at least three of four criteria (i.e., tolerance, withdrawal, persistent desire, or an unsuccessful attempt to reduce consumption and persistent use despite adverse psychologic or physical consequences). Of 99 people screened, 27 were evaluated by means of a structured psychiatric interview modified for the diagnosis of caffeine dependence; 16 of those subjects (59%) met the criteria. In a second phase of the study, 11 of the 16 caffeine-dependent individuals participated in a 2-day double-blind crossover study of caffeine deprivation. Nine showed evidence of caffeine withdrawal during the placebo phase, a finding that validated one of the criteria for the diagnosis of dependence.

CAFFEINE WITHDRAWAL

12 The frequency of the caffeine withdrawal syndrome is not well known, but it may be common. Withdrawal can occur when individuals who previously have been consuming caffeine on a regular basis suddenly discontinue its intake.[59] The syndrome can be characterized by the occurrence of headache, drowsiness, fatigue, and sometimes impaired psychomotor performance, difficulty concentrating, nausea, excessive yawning, and craving. These symptoms usually appear within 18 to 24 hours of discontinuation of intake, corresponding to the time required for the drug to leave the body.

The caffeine withdrawal headache is somewhat unique, starting with a sense of fullness in the head and progressing to throbbing and diffuse pain that is made worse by movement. The maximum intensity of the pain occurs 3 to 6 hours after beginning.

When caffeine is reintroduced, relief of withdrawal symptoms tends to occur within 30 to 60 minutes. At present, this appears to be the most effective "treatment" for the caffeine-withdrawal syndrome.

EFFECT ON SLEEP

Caffeine interferes with sleep in most nontolerant individuals.[51,52] Once tolerance has developed, people are much less likely to self-report sleep abnormalities, or they may sense that the insomnia has disappeared altogether. To illustrate, 53% of those consuming less than 250 mg/day agreed that caffeine before bedtime would prevent sleep, compared with 43% of those consuming 250 to 749 mg/day, and only 22% of those taking 750 mg/day or more. Even though the higher-level consumers denied that caffeine interferes with their sleep, studies done in the sleep laboratory confirm that caffeine consumers do have greater sleep latency, more frequent awakenings, and altered sleep architecture, and that these effects are dose related.

CAFFEINE DURING PREGNANCY

Over the years there has been much discussion on whether or not caffeine intake during pregnancy is harmful to the developing fetus. Results of research have been mixed, but in general, caffeine has not been shown to be a potent and consistent teratogen. Kuczkowski[60] recently published a review article highlighting the implications of caffeine intake in pregnancy, reviewing the latest evidence-based information available on this subject, and offering recommendations for practitioners providing peripartum care to expectant mothers who consume caffeine.

Based on the data reviewed, the author concluded that for the healthy pregnant adult, moderate daily caffeine intake at a dose level up to 400 mg/day (equivalent to 6 mg/kg body weight per day in a 65-kg [143 lb] person) is not associated with adverse effects such as general toxicity, cardiovascular effects, effects on bone status and calcium balance, changes in adult behavior, increased incidence of cancer, or effects on fertility. The study did not identify any significant positive associations between maternal caffeine consumption and cardiovascular malformations.

The March of Dimes advises women to limit their caffeine intake to less than 200 mg per day. This recommendation was prompted by the results of a study published in March 2008[61] reporting that pregnant women who consumed 200 mg or more of caffeine a day had double the risk of miscarriage compared with those who had no caffeine. Criticism of this study was swift to follow, and its conclusions have been called into question.

CAFFEINE AND HEADACHES

A recent Norwegian study[62] investigated the association between caffeine consumption and headache type and frequency in the general adult population. The results were based on cross-sectional data from 50,483 (55%) out of 92,566 invited participants aged greater than or equal to 20 years. A weak but significant association (OR, 1.16; 95% CI, 1.09–1.23) was found between high caffeine consumption and prevalence of infrequent headache. In contrast, headache greater than 14 days/month was less likely among individuals with high caffeine consumption compared to those with low caffeine consumption. The authors speculate that their results may indicate that high caffeine consumption changes chronic headache into infrequent headache due to the analgesic properties of caffeine. Alternatively, chronic headache sufferers tend to avoid intake of caffeine to not aggravate their headaches, whereas individuals with infrequent headache are less aware that high caffeine use can be a cause.

TREATMENT

Caffeinism

Caffeinism is treated by reducing or discontinuing the drug. It may be necessary to wean the patient off the drug gradually because going "cold turkey" can produce such serious symptoms that the drug must be restarted. Decaffeinated beverages can be substituted slowly for the caffeinated type. However, relapses are less likely to occur when the drug is discontinued all at once, probably because of the considerable self-discipline required to continue weaning the drug when one knows that an increase in dose will cause the symptoms to abate.

Patients with cardiovascular disease, especially arrhythmias, history of stroke or transient ischemic attacks should refrain totally. Patients with peptic ulcer disease, bipolar mood disorder, and schizophrenia should also be encouraged to avoid caffeine altogether.

The reader wishing more information about treatment of caffeine withdrawal should consult the systematic review by Juliano and Griffiths.[51] A review of research on coffee and its health effects has also been published and should be consulted for in-depth discussion of this issue.[63]

CONCLUSIONS

Use of alcohol, tobacco, and caffeine is so commonly accepted in our society that people take notice only when their use causes serious problems. When problems do occur, the human and economic costs are enormous. Healthcare professionals must be committed to helping people free themselves of the addictions that can occur with these common drugs.

CHAPTER 76

Schizophrenia

M. LYNN CRISMON, TAMI R. ARGO, AND PETER F. BUCKLEY

KEY CONCEPTS

1. The pathophysiology of schizophrenia may occur in one or more different neurotransmitter systems.
2. The clinical presentation of schizophrenia is characterized by positive symptoms, negative symptoms, and impairment in cognitive functioning.
3. Comprehensive care for individuals with schizophrenia must occur in the context of a multidisciplinary mental healthcare environment that offers psychotropic medication management and comprehensive psychosocial services.
4. A thorough patient evaluation (e.g., history, mental status exam, physical exam, psychiatric diagnostic interview, and laboratory analysis) should occur to establish a diagnosis of schizophrenia and to identify potential co-occurring disorders, including substance abuse and general medical disorders.
5. Given that it is challenging to differentiate among antipsychotics based upon efficacy, side-effect profiles become important in choosing an antipsychotic for an individual patient.
6. Pharmacotherapy algorithms should emphasize monotherapies with antipsychotics of optimal efficacy: side-effect ratios and progress to medications with greater side-effect risks and then to combination regimens only in the most treatment-resistant patients.
7. Adequate time on a given medication at a therapeutic dose is the most important variable in predicting medication response.
8. Long-term, maintenance antipsychotic treatment is necessary for the vast majority of patients with schizophrenia in order to prevent relapse.
9. Thorough patient and family psychoeducation should occur, including education about the illness, symptoms, prognosis, medication, psychosocial treatments, and methods to improve adaptive functioning.
10. Pharmacotherapy decisions should be guided by systematic monitoring of patient symptoms, preferably with the use of brief symptom rating scales.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Schizophrenia is one of the most complex and challenging of psychiatric disorders. It represents a heterogeneous syndrome of disorganized and bizarre thoughts, delusions, hallucinations, inappropriate affect, and impaired psychosocial functioning. From the time that Kraepelin first described dementia praecox in 1896 until publication of the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* in 2000, the description of this illness has continuously evolved.[1] Scientific advances that increase our knowledge of central nervous system (CNS) physiology, pathophysiology, and genetics will likely improve our understanding of schizophrenia in the future.

EPIDEMIOLOGY

According to the Epidemiologic Catchment Area Study, the lifetime prevalence of schizophrenia using strict diagnostic criteria ranges from 0.6% to 1.9%. If a broader definition is used, the lifetime rate rises to 2% to 3%.[2] The worldwide prevalence of schizophrenia is remarkably similar among most cultures. Schizophrenia most commonly has its onset in late adolescence or early adulthood and rarely occurs before adolescence or after the age of 40 years. Although the prevalence of schizophrenia is equal in males and females, the onset of illness tends to be earlier in males. Males most frequently have their first episode during their early 20s, whereas with females it is usually during their late 20s to early 30s.[1,3]

ETIOLOGY

Although the etiology of schizophrenia is unknown, research has demonstrated various abnormalities in brain structure and function.[4] However, these changes are not consistent among all individuals with schizophrenia The cause of schizophrenia is likely multifactorial; that is, multiple pathophysiologic abnormalities can play a role in producing the similar but varying clinical phenotypes we refer to as schizophrenia.

A neurodevelopmental model has been evoked as one possible explanation for the etiology of schizophrenia.[4] This model proposes that schizophrenia has its origins in some as yet unknown in utero disturbance, possibly occurring during the second trimester of pregnancy. Evidence for this is provided by the abnormal neuronal migration demonstrated in studies of schizophrenic brains. This "schizophrenic lesion" can result in abnormalities in cell shape, position, symmetry, connectivity, and functionally to the

development of abnormal brain circuits.[4] Changes are consistent with a cell migration abnormality during the second trimester of pregnancy, and some studies associate upper respiratory infections during the second trimester of pregnancy with a higher incidence of schizophrenia.[5] Other studies show a relationship between obstetric complications or neonatal hypoxia and schizophrenia. Some studies associate low birth weight (less than 2.5 kg [5.5 lb]) with schizophrenia.[2] Maternal stress, perhaps related to the effects of circulating glucocorticoids in utero, may be a risk factor for schizophrenia. Maternal "stress" could derive from a variety of external and internal noxious events (malnutrition, infection, etc.). The resulting secondary "synaptic disorganization" associated with such insults is thought not to produce overt clinical manifestations of psychosis until adolescence or early adulthood because this is the corresponding time period of neuronal maturation.

Although studies have shown decreased cortical thickness and increased ventricular size in the brains of many patients with schizophrenia, this occurs in the absence of widespread gliosis.[4] One hypothesis is that obstetric complications and hypoxia, in combination with a genetic predisposition, could activate a glutamatergic cascade that results in increased neuronal pruning. It is hypothesized that this genetic predisposition may be related to genes controlling *N*-methyl-D-aspartate (NMDA) receptor activity. As a part of the normal neurodevelopmental process, pruning of dendrites occurs. In normal individuals, approximately 35% of the peak number of dendrites at 2 years of age are pruned by midadolescence. Some studies have shown a higher percentage of pruning in individuals with schizophrenia. Furthermore, synaptic pruning predominantly involves glutamatergic dendrites. Hypoxia or other prenatal insult can result in a decreased number of basal neurons from which to start, and glutamatergic activation can exaggerate the pruning process.[6]

Numerous studies have shown neuropsychologic abnormalities and impairment in reaching normal motor milestones and abnormal movements in young children who later develop schizophrenia.[3] Abnormalities in brain function occur long before the onset of psychotic symptomatology and provide empiric evidence for schizophrenia being a neurodevelopmental disorder.[4] However, the progressive clinical deterioration in many patients suggests that this illness can also have a neurodegenerative component. This is consistent with recent brain imaging studies that show deteriorative brain changes in patients with frequent relapses.[2,4,7] Schizophrenia may be neither neurodevelopmental or neurodegenerative in origin, but rather an illness exhibiting neurodegenerative propensity based on a vulnerable neurodevelopmental predisposition.[2,8,9]

GENETICS

Although a specific abnormality has not been discovered, evidence suggests a genetic basis for schizophrenia. Although the risk of developing schizophrenia is 0.6% to 1.9% in the U.S. population, the risk is approximately 10% if a first-degree relative has the illness and 3% if a second-degree relative has the illness.[2,10] If both parents have schizophrenia, the risk of producing a schizophrenic offspring increases to approximately 40%. Twin studies in dizygotic twins report that the risk of the second twin developing schizophrenia if one twin has the illness is between 12% and 14%. However, in monozygotic twins the risk increases to 48%.[10] Numerous adoption studies indicate that the risk for schizophrenia lies with the biologic parents, and change in the environment during the child's developmental stages does not alter this. If schizophrenia occurs in siblings, the onset of illness tends to occur at the same age in each, thus lessening the possibility of an environmental precipitant. A search for a genetic linkage in schizophrenia has been difficult, and any genetic etiologies in schizophrenia are likely heterogeneous, but present with similar phenotypes. Potential loci have been identified on chromosomes 6, 8, 13, and 22.[10] The study of the genetics of schizophrenia has become increasingly molecular in focus.[2,11] Recent work has shown that polymorphism in the *VAL/MET* alleles of the catecholamine-O-methyl transferase gene can explain some of the frontal lobe functional deficits in a subset of individuals with schizophrenia.[10] Other recent studies have shown abnormalities in several genes that code for neurodevelopment and for trophic factors.[10–12] For example, dysbindin is a neurodevelopmental protein gene that is found on chromosome 6. Alleles associated with decreased dysbindin RNA in the dorsolateral prefrontal cortex have been reported in patients with schizophrenia and their families.[13] Another recent gene-wide linkage scan of a large pedigree showed increased signal at chromosome 8p, close to the gene that encodes for neuregulin—another neurodevelopmental gene.[14] Of particular excitement in the field has been the discovery of an overexpression of copy number variants (CNVs) in schizophrenia.[11,12,14] This work has fueled other new large-scale genetic studies that are ongoing in an attempt to replicate these findings.

PATHOPHYSIOLOGY

Computed axial tomography (CAT) scans and magnetic resonance imaging (MRI) studies show increased ventricular size, particularly in the third and lateral ventricles, in subtypes of schizophrenics. Recent studies also show a small decrease in brain size compared to matched controls. These changes appear to be consistent with brain asymmetry, the ventricular enlargement being most pronounced in the left temporal horn, and the decreased cortical size being most obvious in the left temporal lobe.[2,7] Not only does premorbid lower hippocampal volume predict onset of symptoms in high-risk individuals, these structural changes can progress throughout the course of the illness.[15] A reduction in medial temporal lobe volume has been reported in high-risk patients after they were scanned, indicating that some brain changes can be associated with the evolution of psychosis. In an extended analysis, high-risk subjects were compared with first-episode chronic schizophrenia and normal control groups according to hippocampal and amygdala volumes at baseline.[16] No difference in MRI volumes between the high-risk subjects and normal controls were observed, irrespective of whether the at-risk patients did or did not progress to overt psychosis. First-episode schizophrenia (but not other psychosis) groups had reduced (left) hippocampal volume. The implication that these changes occur during transition is intriguing and accords well with the notion of psychosis as a biologically toxic event. Changes in hippocampal volume may correspond with impairment in neuropsychologic testing.[2] Rather than a decrease in the number of neurons in affected brain areas, a decrease in axonal and dendritic communications between cells can result in a loss of connectivity that can be important with respect to neuronal adaptivity and CNS homeostasis.[2,4] These changes are likely consistent with the evidence for abnormal neuronal pruning.[4]

NEUROTRANSMITTER CHANGES

Four dopaminergic tracts are of primary interest. Table 76–1 outlines the origin, innervation, and primary functional activity of each tract, as well as the effects of dopamine (DA) antagonists.[6]

Evidence supports the presence of a DA-receptor defect in schizophrenia. Numerous positron emission tomography (PET) studies have shown regional brain abnormalities, including increased glucose metabolism in the caudate nucleus and decreased blood flow and glucose metabolism in the frontal lobe and left temporal lobe.[3] This can indicate dopaminergic hyperactivity in the head of the

TABLE 76-1 Dopaminergic Tracts and Effects of Dopamine Antagonists

Dopamine Tract	Origin	Innervation	Function	Dopamine Antagonist Effect
Nigrostriatal	Substantia nigra (A9 area)	Caudate nucleus Putamen	Extrapyramidal system, movement	Movement disorders
Mesolimbic	Midbrain ventral tegmentum (A10 area)	Limbic areas (e.g., amygdala, olfactory tubercle, septal nuclei) cingulate gyrus	Arousal, memory, stimulus processing, motivational behavior	Relief of psychosis
Mesocortical	Midbrain ventral tegmentum (A10 area)	Frontal and prefrontal lobe cortex	Cognition, communication, social function, response to stress	Relief of psychosis Akathisia
Tubero-infundibular	Hypothalamus	Pituitary gland	Regulates prolactin release	Increased prolactin concentrations

caudate nucleus and dopaminergic hypofunction in the frontotemporal regions. PET studies using dopamine-2 (D_2)-specific ligands suggest increased densities of D_2 receptors in the head of the caudate nucleus with decreased densities in the prefrontal cortex.[3,4] PET studies assessing dopamine-1 (D_1) function suggest that subpopulations of schizophrenics may have decreased densities of D_1 receptors in the caudate nucleus and the prefrontal cortex. Hypofrontality can be associated with lack of volition and cognitive dysfunction, core features of schizophrenia. It is unknown whether these changes represent a primary event or secondary processes related to other pathophysiologic abnormalities in schizophrenia. Because of the heterogeneity in the clinical presentation of schizophrenia, it has been suggested that the DA hypothesis can be more applicable to "neuroleptic-responsive psychosis," with multiple different etiologies possibly being responsible for causing schizophrenia.[2] Attempts have been made to develop relationships between these abnormal findings and behavioral symptoms present in schizophrenic patients. The positive symptoms are possibly more closely associated with DA-receptor hyperactivity in the mesocaudate, whereas negative symptoms and cognitive impairment are most closely related to DA-receptor hypofunction in the prefrontal cortex. Presynaptic D_1 receptors in the prefrontal cortex are thought to be involved in modulating glutamatergic activity, and this can be important with regard to working memory in individuals with schizophrenia.[2]

The glutamatergic system is one of the most widespread excitatory neurotransmitter systems in the brain. Alterations in its function, either hypo- or hyperactivity, can result in toxic neuronal reactions.[3] Dopaminergic innervation from the ventral striatum decreases the limbic system's inhibitory activity (perhaps through γ-aminobutyric acid [GABA] interneurons); thus, dopaminergic stimulation increases arousal. The corticostriatal glutamate pathways have the opposite effect, inhibiting dopaminergic function from the ventral striatum, therefore allowing the limbic system to have increased inhibitory activity. Descending glutamatergic tracts interact with dopaminergic tracts directly as well as through GABA interneurons. Glutamatergic deficiency produces symptoms similar to those of dopaminergic hyperactivity and possibly those seen in schizophrenia. Clinical support for this comes from the fact that phencyclidine, a potent psychotomimetic, is a noncompetitive antagonist at the NMDA receptor, a major glutamate receptor. Similarly, abuse of ketamine, a veterinary anesthetic, can resemble schizophrenia. Ketamine, a competitive antagonist at glutamatergic NMDA receptors, has been shown to lead to reduction in D_1 neurotransmission through glutamatergic inhibition of DA release.[17] It is proposed that schizophrenia may involve some in utero assault that leads to a developmental defect in NMDA receptor function—so-called NMDA hypofunction. This defect is proposed to have latent clinical expression with the psychotic manifestations from NMDA hypofunction not being seen until late adolescence or early adulthood. It has been shown that excess D_2 stimulation can impair NMDA transmission via GABAergic neurons. Thus the use of antipsychotic drugs may indirectly enhance glutamatergic transmission.[2]

Serotoninergic receptors are present on dopaminergic axons, and stimulation of these receptors decreases DA release, at least in the striatum.[6] Although somewhat more diffuse, the distribution of serotonergic neurons is similar to that of dopaminergic neurons, thus allowing these two neurotransmitter systems to innervate the same areas. In fact, 5-hydroxytryptamine$_2$ (serotonin-2; 5-HT_2) receptors and D_4 receptors have been found to be colocalized in the cortex.[2,6] Patients with schizophrenia with abnormal brain scans have higher whole-blood 5-HT concentrations, and these concentrations are correlated with increased ventricular size.[18] Second-generation antipsychotics (SGA), also known as atypical antipsychotics, with potent 5-HT_2 receptor antagonist effects reverse worsening of symptomatology induced by 5-HT agonists in patients with schizophrenia.[18]

1 Schizophrenia is a complex disorder, and multiple etiologies likely exist. Based on current knowledge, it is naive to think that any currently proposed etiology can adequately explain the genesis of this complex disease. Molecular research involving genetically determined subtle changes in G proteins, protein metabolism, and other subcellular processes can eventually identify the biologic disturbances associated with schizophrenia.[2,4,8]

CLINICAL PRESENTATION

Schizophrenia is the most common functional psychosis, and great variability occurs in clinical presentation. Despite numerous attempts to portray a stereotype in movies and on television, the stereotypic schizophrenic essentially does not exist. Moreover, schizophrenia is not a"split personality." It is a chronic disorder of thought and affect with the individual having a significant disturbance in interpersonal relationships and ability to function in society.

The first psychotic episode can be sudden in onset with few premorbid symptoms, or commonly can be preceded by withdrawn, suspicious, peculiar behavior (schizoid). During acute psychotic episodes, the patient loses touch with reality, and in a sense, the brain creates a false reality to replace it. Acute psychotic symptoms can include hallucinations (especially hearing voices), delusions (fixed false beliefs), and ideas of influence (beliefs that one's actions are controlled by external influences). Thought processes are disconnected (loose associations), the patient may not be able to carry on logical conversation (alogia), and can have simultaneous contradictory thoughts (ambivalence). The patient's affect can be flat (no emotional expression), or it can be inappropriate and labile. The patient is often withdrawn and inwardly directed (autism). Uncooperativeness, hostility, and verbal or physical aggression can be seen because of the patient's misperception of reality. Self-care skills are impaired, and the patient is frequently dirty, unkempt, and in general has poor hygiene. Sleep and appetite are often disturbed. When the acute psychotic episode remits, the patient typically has residual features. This is an important point in differentiating schizophrenia from other psychotic disorders. Although residual

symptoms and their severity vary, patients can have difficulty with anxiety management, suspiciousness, and lack of volition, motivation, insight, and judgment. Therefore, they often have difficulty living independently in the community. Because of poor anxiety management and suspiciousness, they are frequently withdrawn socially, and have difficulty forming close relationships with others. In addition, impaired volition and motivation contribute to poor self-care skills and make it difficult for the patient with schizophrenia to maintain employment.

Patients with schizophrenia frequently experience a lack of historicity, or difficulty in learning from their experiences. They can repeatedly make the same mistakes in social conduct and situations requiring judgment. They have difficulty understanding the importance of treatment, including medications, in maintaining their ability to function in society. Therefore, they tend to discontinue medications and other treatments, and this increases the risk of relapse and rehospitalization. The co-occurrence of substance abuse (predominantly alcohol or polysubstance—alcohol, cannabis, cocaine) in patients with schizophrenia is very common and is another frequent reason for relapse and hospitalization.[1,2] This effect can be caused by direct toxic effects of these drugs on the brain,[17] but is also caused by the medication nonadherence that is associated with substance abuse.

Although the course of schizophrenia is variable, the long-term prognosis for many patients is poor. It is marked by intermittent acute psychotic episodes and impaired psychosocial functioning between acute episodes, with most of the deterioration in psychosocial functioning occurring within 5 years after the first psychotic episode.[19,20] By late life, the patient can appear "burned out," that is, the patient ceases to have acute psychotic episodes, but residual symptoms persist. In a subpopulation of patients, probably 5% to 15%, psychotic symptoms are nearly continuous, and response to antipsychotics is poor.[19]

Schizophrenia is a chronic disorder, and the patient's history must be carefully assessed for dysfunction that has persisted for longer than 6 months. After their first episode, patients with schizophrenia rarely have a level of adaptive functioning as high as before the onset of the disorder. Table 76–2 summarizes the *DSM-IV-TR* criteria.[1]

TABLE 76-2 DSM-IV-TR Diagnostic Criteria for Schizophrenia

A. Characteristic symptoms: Two or more of the following, each persisting for a significant portion of at least a 1-month period:
   (1) Delusions
   (2) Hallucinations
   (3) Disorganized speech
   (4) Grossly disorganized or catatonic behavior
   (5) Negative symptoms

Note: Only one criterion A symptom is required if delusions are bizarre or if hallucinations consist of a voice keeping a running commentary on the person's behavior or two or more voices conversing with each other.

B. Social/occupational dysfunction: For a significant portion of the time since onset of the disorder, one or more major areas of functioning such as work, interpersonal relations, or self-care are significantly below the level prior to onset.

C. Duration: Continuous signs of the disorder for at least 6 months. This must include at least 1 month of symptoms fulfilling criterion A (unless successfully treated). This 6 months may include prodromal or residual symptoms.

D. Schizoaffective or mood disorder has been excluded.

E. Disorder is not due to a medical disorder or substance use.

F. If a history of a pervasive developmental disorder is present, there must be symptoms of hallucinations or delusions present for at least 1 month.

Conceptual disorganization	Avolition	

From American Psychiatric Association,[1] Lehman et al.,[19] and Velligan et al.[119]

2 The *DSM-IV-TR* classifies the symptoms of schizophrenia into two categories: positive and negative. Recently greater emphasis has been placed on a third symptom category, cognitive dysfunction (Table 76–3).[19] The areas of cognition found to be abnormal in schizophrenia include attention, working memory, and executive function. Positive symptoms have traditionally attracted the most attention and are the ones most improved by antipsychotics. However, negative symptoms and impairment in cognition are more closely associated with poor psychosocial function. Along with these characteristic features of schizophrenia, many patients also have comorbid psychiatric and general medical disorders.[19,20] These include depression, anxiety disorders, substance abuse, and general medical disorders like respiratory disorders and metabolic disturbances. These comorbidities substantially complicate the clinical presentation and course of schizophrenia.

It has been suggested that symptom complexes can correlate with prognosis, cognitive functioning, structural abnormalities in the brain, and response to antipsychotic drugs. Negative symptoms and cognitive impairment can be more closely associated with prefrontal lobe dysfunction and positive symptoms with temporolimbic abnormalities. Many patients demonstrate both positive and negative symptoms. Patients with negative symptoms frequently have more antecedent cognitive dysfunction, poor premorbid adjustment, low level of educational achievement, and a poorer overall prognosis.[19]

TREATMENT

DESIRED OUTCOME

Pharmacotherapy is the mainstay of treatment in schizophrenia, and it is impossible in most patients to implement effective psychosocial rehabilitation programs in the absence of antipsychotic treatment.[19] 3 A pharmacotherapeutic treatment plan should be developed that delineates drug-related aspects of therapy. Most deterioration in psychosocial functioning occurs during the first 5 years after the initial psychotic episode, and treatment should be particularly assertive during this period.[19,20] Explicit end points should be defined, including realistic goals for the target symptoms most likely to respond, and the relative time course for response.[19,20] Other goals include avoiding unwanted side effects, using the minimum effective dose, emphasizing adequate duration of treatment as a primary variable in determining response, and limiting augmentation medications to nonresponsive patients.

NONPHARMACOLOGIC THERAPY

Psychosocial rehabilitation programs oriented toward improving patients' adaptive functioning are the mainstay of nondrug treatment for schizophrenia. These programs can include case management, psychoeducation, targeted cognitive therapy, basic living skills, social skills training, basic education, work programs, supported housing, and financial support. In particular, programs aimed at employment and housing have been the more effective

TABLE 76-4 Psychotherapeutic Approaches to the Treatment of Schizophrenia

interventions and are considered "best practices." Programs that involve families in the care and life of the patient have been shown to decrease rehospitalization and improve functioning in the community. For particularly low-functioning patients, assertive intervention programs, referred to as *active community treatment* (ACT), are effective in improving patients' functional outcomes. ACT teams are available on a 24-hour basis and work in the patient's home and place of employment to provide comprehensive treatment, including medication, crisis intervention, daily living skills, and supported employment and housing.[19,20] Medication treatment cannot be successful without proper attention to these other aspects of care. People with schizophrenia need comprehensive care, with coordination of services across psychiatric, addiction, medical, social, and rehabilitative services. The level of coordination in the United States is often insufficient, and patients become at risk to "fall through the cracks." Recent national policy documents have called for greater coordination of care.[21,22] Additionally, emphasis is growing on the role that the person himself or herself plays in a recovery-based system of care, where the person's lifetime aspirations and goals become the center of care, rather than symptom reduction being the primary focus. This recovery-based approach recognizes the strengths and resilience of people with schizophrenia.[23] It also acknowledges how people with schizophrenia can also be a support to others who are coping with the illness.[24] It is important to frame clinical decision making in the context of a mutual process involving patient and clinician-rather than a unilateral "here's a prescription…please take these tablets" approach. Also, it is increasingly recognized that cognitive behavioral therapy can help some patients. A list of psychotherapeutic approaches to the treatment of schizophrenia is given in Table 76–4.

PHARMACOLOGIC THERAPY

Assessment Prior to Treatment

4 The importance of initial accurate diagnostic assessment cannot be overemphasized. A thorough mental status examination, psychiatric diagnostic interview, physical and neurologic examination, complete family and social history, and laboratory workup must be performed to confirm the diagnosis and exclude general medical or substance-induced causes of psychosis. Laboratory tests, biologic markers, and commonly available brain imaging techniques do not assist in diagnosis or selection of medication. A pretreatment patient workup is important in not only excluding other pathology, but in serving as a baseline for monitoring potential medication-related side effects, and should include vital signs, complete blood count, electrolytes, hepatic function, renal function, electrocardiogram, fasting serum glucose, serum lipids, thyroid function, and urine drug screen.

SGAs (with the exception of clozapine) are first-line agents in the treatment of schizophrenia.[19,25] No absolute criterion distinguishes atypical (second generation) from typical (traditional, conventional, or first generation) antipsychotics, and no universally accepted definition exists for an atypical antipsychotic.[18] Therefore, *second-generation antipsychotic* is a more appropriate term. Common to all definitions is the ability of the drug to produce antipsychotic response with few or no acutely occurring extrapyramidal side effects. Other attributes that have been ascribed to SGAs include enhanced efficacy, particularly for negative symptoms and cognition; absence or near absence of propensity to cause tardive dyskinesia; and lack of effect on serum prolactin.[18] To date, the only approved SGA that fulfills all of these criteria is clozapine.[18] Although early studies suggested that SGAs might have a superior effect on negative symptoms and cognition, this has not been confirmed in more recent studies.[2,19,25] The major advantage of atypical antipsychotics is their lower risk of neurologic side effects, particularly effects on movement. However, this is offset by increased risk of metabolic side effects with some SGAs, including weight gain, hyperlipidemias, and diabetes mellitus. 5 Side-effect profiles differ among antipsychotics, and this information in combination with individual patient characteristics should be used in deciding which drug to use in an individual patient. Information from the algorithm (Fig. 76–1) and the adverse effects sections should be used in arriving at this decision.

Results from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study indicate that olanzapine, compared with quetiapine, risperidone, ziprasidone, and the FGA perphenazine, has modest superiority in maintenance therapy when treatment persistence is the primary clinical outcome.[27] However, increased metabolic adverse effects occurred with olanzapine.

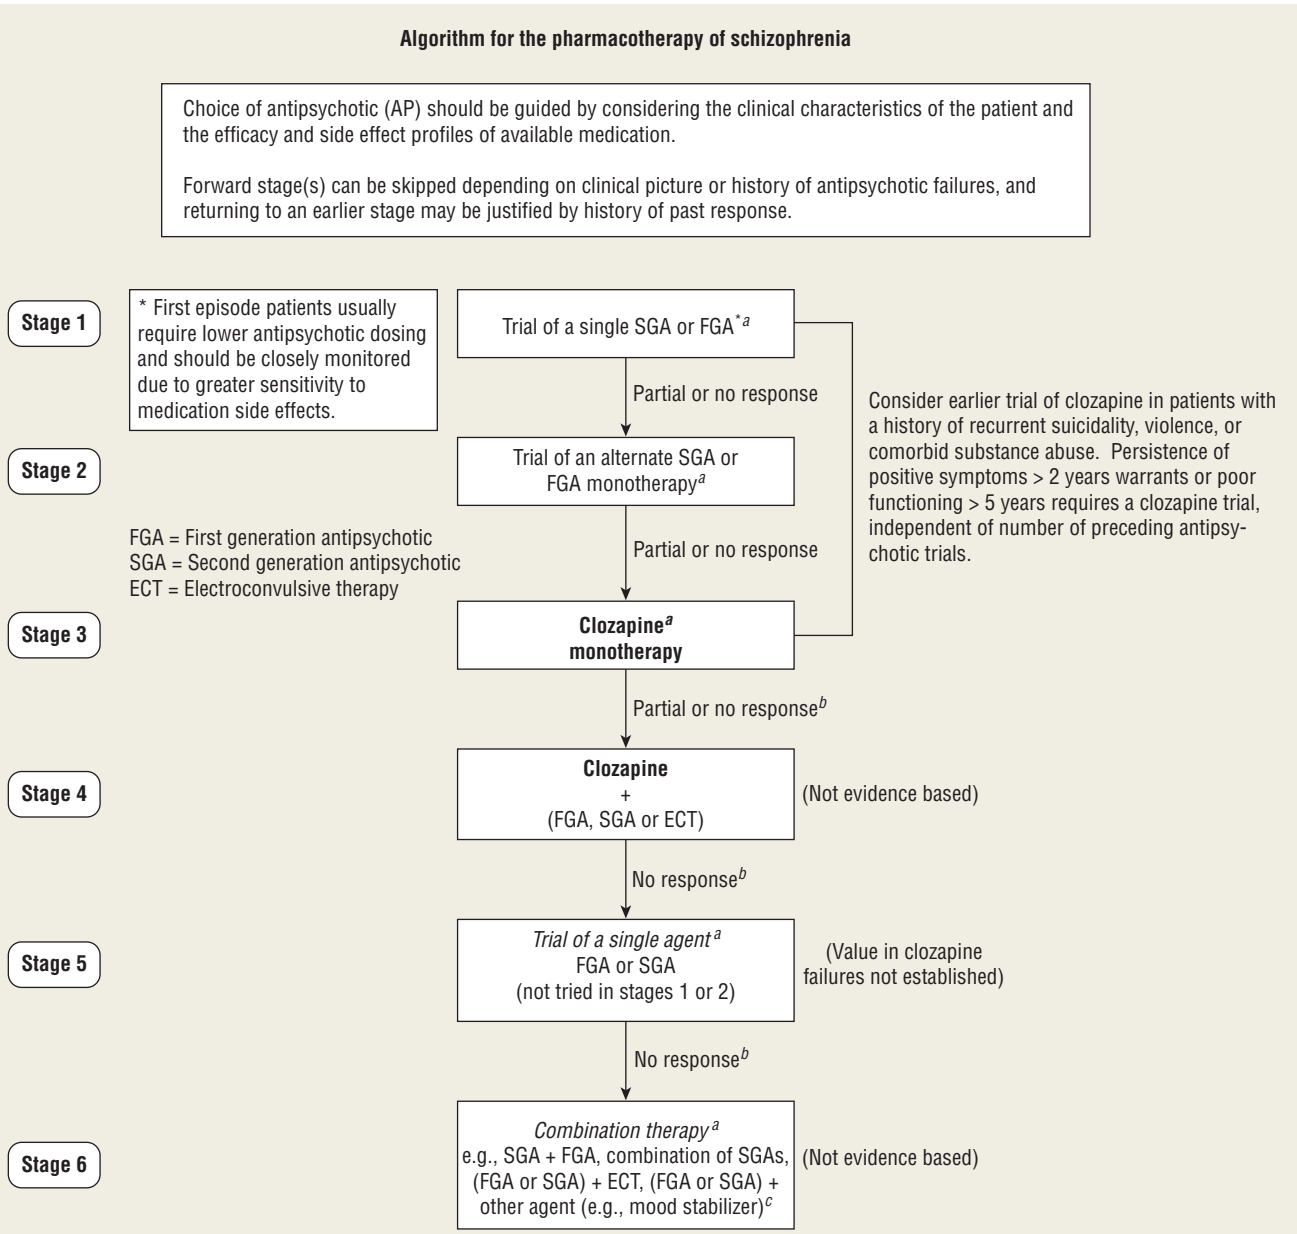
No known differences exist in efficacy between low- and high-potency FGAs. Previous patient or family history of response to an antipsychotic is helpful in the selection of an agent. Traditional dosage equivalents (expressed in "chlorpromazine equivalent dosages"—the equipotent dosage of any traditional FGA compared with 100 mg of chlorpromazine) can assist in determining the effective dosage range if the need arises to treat a patient with a different FGA. However, because SGAs differ in mechanism of action, the dose equivalents have little relevance when comparing dosages of SGAs. Table 76–5 lists antipsychotics and their usual dosage ranges.

PHARMACOTHERAPEUTIC ALGORITHM

6 Figure 76–1 outlines a suggested pharmacotherapeutic algorithm for schizophrenia.[25,26,28] Stage 1 of the treatment algorithm applies to those patients experiencing their first episode of schizophrenia or to patients off of medications and re-entering treatment who do not have a history of nonresponse or nontolerance with antipsychotics. The clinician needs to evaluate the relative risk of extrapyramidal side effects (EPS) with FGAs versus the risk of metabolic side effects with different SGAs in making a decision for drug selection. The 2009 PORT recommendations do not recommend the use of olanzapine in first episode because of weight gain and metabolic side effects.[26] Stage 2 addresses pharmacotherapy in a patient who had inadequate clinical improvement with the antipsychotic used in stage 1. Stage 2 recommends an alternate antipsychotic monotherapy with the exception of clozapine.[25,26]

Because of safety concerns and the need for white blood cell (WBC) monitoring, it is recommended that patients be tried on two different monotherapy antipsychotic trials before proceeding to a trial of clozapine (stage 3).[25,26] Clozapine has superior efficacy in decreasing suicidal behavior, and it should be considered as a higher treatment option in the suicidal patient.[25,26] Clozapine can also be considered earlier in treatment in patients with a history of violence or comorbid substance abuse.[25,26]

Stage 4 of the treatment algorithm includes clozapine and augmentation with either a FGA, SGA, or electroconvulsive therapy (ECT).[25] Treatment algorithm recommendations after stage 3



[a]If patient is inadequately adherent at any stage, the clinician should assess contributing factors and consider switching to long-acting monotherapy antipsychotic treatment,

[b]A treatment refractory evaluation should be performed to reexamine diagnosis, substance abuse, medication adherence, and psychosocial stressors. cognitive behavioral therapy and other psychosocial augmentations should be considered.

[c]Whenever a second medication is added to an antipsychotic (other than clozapine) for the purpose of improving psychotic symptoms, the patient is considered to be in stage 6.

FIGURE 76-1. Patient entry into the algorithm is determined by individual patient history, clinical presentation, and consideration of potential side-effect risk. Either first episode patients or patients who have been off of medications and are reentering treatment with no history of poor response to antipsychotics are entered at stage 1. Algorithm stages can be skipped if clinically appropriate, and one can go back stages if indicated. In general, inadequately responding patients should not remain in stages 1 or 2 longer than 12 weeks at therapeutic doses. Stage 3 should be at least 6 months. In stages 4, 5, and 6, a 12-week trial is recommended, and if there is greater than or equal to 20% improvement in positive symptoms at week 12, the medication trial warrants extension for an additional 12 weeks with dose titration as clinically warranted. The levels of evidence for algorithm recommendations are as follows: stage 1, level A for efficacy for both first-generation antipsychotics (FGAs) and second-generation antipsychotics (SGAs); stage 2, level A; stage 3, level A; stage 4, level C; stage 5, level C; stage 6, level C. Level A is supported by one or more randomized controlled trials. Level B is supported by large cohort studies, epidemiologic studies, and so on. Level C is supported only by case series, case reports, or expert opinion. *(Created based upon references 25, 26, 28.)*

TABLE 76-5 Available Antipsychotics: Doses and Dosage Forms

Generic Name	Trade Name	Traditional Equivalent Dose (mg)	Usual Dosage Range (mg/day)	Manufacturer's Maximum Dose (mg/day)[a]	Dosage Forms[b]
First-generation antipsychotics (traditional or typical antipsychotics)					
Chlorpromazine	Thorazine	100	100–800	2,000	T,L,LC,I,C-ER,S
Fluphenazine	Prolixin	2	2–20	40	T,L,LC,I,LAI
Haloperidol	Haldol	2	2–20	100	T,LC,I,LAI

Molindone	Moban	10	10–100	225	T,LC
Perphenazine	Trilafon	10	10–64	64	T,LC,I
Thioridazine	Mellaril	100	100–800	800	T,LC
Thiothixene	Navane	4	4–40	60	C,LC
Trifluoperazine	Stelazine	5	5–40	80	T,LC,I
Second-generation antipsychotics (atypical antipsychotics)					
Aripiprazole	Abilify	NA	15–30	30	T,O,L
Asenapine	Saphris	NA	10-20	20	SL
Clozapine	Clozaril	NA	50–500	900	T,O
Iloperidone	Fanapt	NA	2–24	24	T
Olanzapine	Zyprexa	NA	10–20	20	T,I,O
Paliperidone	Invega	NA	3–9	12	ER
Paliperidone palmitate	Invega Sustenna	NA	39-234	234	LAI
Quetiapine	Seroquel	NA	250–500	800	T
Risperidone	Risperdal	NA	2–8	16	T,O,L
Risperidone	Risperdal Consta	NA	25–50 mg every 2 wk	50	LAI
Ziprasidone	Geodon	NA	40–160	200	C,I

[a]NA. This parameter does not apply to atypical antipsychotics.
[b]C, capsule; ER or SR, extended or sustained release; I, injection; L, liquid solution, elixir, or suspension; LC, liquid concentrate; LAI, long-acting injectable; O, orally disintegrating tablets; R, rectal suppositories; SL, sublingual tablet; T, tablet.

(i.e., clozapine monotherapy) are based more on anecdotal experiences and expert opinion than on empirical research.[25] In general, patients who experience poor improvement with clozapine do not respond well with other antipsychotic monotherapies (stage 5), thus the primary reason that clozapine augmentation is recommended at stage 4. Stage 6 combination pharmacotherapy interventions are not evidence based and should only be implemented with time limited, careful evaluation of a patient's symptom response and discontinuation of the combination if improvement does not occur.[25]

If partial or poor adherence contributes to inadequate clinical improvement, then long-acting injectable antipsychotics should be considered.[19,20,26] In addition to individuals who are identified as partially adherent, some patients may elect for long-acting injections instead of taking daily oral medication. A long-acting injectable antipsychotic can be substituted for an oral antipsychotic at any point in the algorithm where it is thought to be indicated.

The use of antipsychotic combinations is controversial, as limited evidence supports increased efficacy for combination antipsychotic treatment.

CLINICAL CONTROVERSY

Significant controversy exists regarding whether to use an FGA or an SGA as first-line treatment in schizophrenia. Although most studies have demonstrated a lower incidence of EPS with SGAs, weight gain and the risk of diabetes mellitus are significant adverse events with some of the SGAs, particularly olanzapine. Tension also exists between policy decision makers who are responsible for managing finite resources and clinicians who see clinical benefits of the SGAs in the patients they treat.

The use of antipsychotic combinations is controversial, as insufficient evidence exists to support their use. Regardless, combination antipsychotics are frequently used by clinicians, and testimonies attest to clinical benefits when a second SGA is added.

PREDICTORS OF RESPONSE

Obtaining a thorough medication history is important, and previous antipsychotic treatment should help guide the selection of drug therapy, in that either a good prior response favors the use of the same agent or a negative prior response suggests the selection of a dissimilar drug. Nonprescription and illicit drug use can influence psychiatric presentation and thus diagnosis or antipsychotic response. Amphetamines and other CNS stimulants, cocaine, corticosteroids, digitalis glycosides, indomethacin, marijuana, pentazocine, phencyclidine, and other drugs can induce psychosis in susceptible individuals or exacerbate psychosis in patients with preexisting psychiatric illness.[29] Patients with schizophrenia who continue to abuse alcohol or drugs usually have a poor response to medications and a poor prognosis. Alcohol, caffeine, and nicotine use potentially results in drug interactions.

Individual differences in patient response have been either proposed or identified, which can be clinically useful predictors of response.[19,20] Acute onset and short duration of illness, presence of acute stressors or precipitating factors, later age of onset, family history of affective illness, and good premorbid adjustment as reflected in stable interpersonal relationships or employment are all predictors of good response.[19,20]

Although controversial, affective symptoms can correlate with an overall good response. Negative symptoms and neuropsychologic deficits related to cognition and neurologic soft signs can correlate with poor antipsychotic response.[19,20] A patient's subjective response within the first 48 hours after being administered an FGA can be associated with drug responsiveness.[30] An initial dysphoric response, demonstrated by stating a dislike of the medication, or feeling worse or zombie-like, combined with anxiety or akathisia-like symptoms, is associated with poor drug response, adverse effects, and nonadherence.

The importance of developing a therapeutic alliance between the patient and the clinician cannot be underestimated. Patients who

form positive therapeutic alliances are more likely to be adherent with all aspects of therapy, experience a better outcome at 2 years, and require smaller antipsychotic doses.

A certain minority of patients fail to benefit from antipsychotic therapy, and their psychosocial functioning can actually worsen. Unfortunately, no accepted method is available to identify these people before treatment.[19,26] Recent evidence suggests that pharmacogenetics can play a role in predicting treatment response, both with respect to symptom improvement and with liability to develop side effects.[30,31] However, insufficient information is available to recommend routine clinical testing.

INITIAL TREATMENT IN AN ACUTE PSYCHOTIC EPISODE

The goals during the first 7 days of treatment should be decreased agitation, hostility, combativeness, anxiety, tension, and aggression, and normalization of sleep and eating patterns. The usual recommendation is to initiate therapy and to titrate dose over the first few days to an average effective dose, unless the patient's physiologic status or history indicates that this dose can result in unacceptable adverse effects. Table 76–5 lists the usual dosage range, and an average dose is typically midrange. Because of increased sensitivity to side effects, particularly extrapyramidal side effects, in first-episode psychotic patients, typical dosing ranges are approximately 50% of the doses used in chronically ill individuals.[25] If "cheeking" of medication is suspected, liquid formulations and orally disintegrating tablets of different antipsychotics are available (see Table 76–5). If a patient has shown absolutely no improvement after 3 to 4 weeks at therapeutic doses, then an alternative antipsychotic should be considered (i.e., moving to the next treatment stage in the algorithm; see Fig. 76–1).[18,25]

Although some clinicians believe that larger daily doses are necessary in more severely symptomatic patients, data are not available to support this practice. Some symptoms, such as agitation, tension, aggression, and increased motor activity, can respond more quickly, but side effects can be more common with higher doses. However, interindividual differences in dosage and patient response do occur. In partial but inadequate responders who are tolerating the chosen antipsychotic, it may be reasonable to titrate above usual dose ranges. However, this tactic should be time-limited (i.e., 2–4 weeks), and if the patient does not achieve further improvement, the dose should either be decreased, or an alternative treatment strategy tried.[32] In general, rapid titration of antipsychotic dosage is not indicated.[32] However, intramuscular antipsychotic administration (e.g., aripiprazole 5.25–9.75 mg IM, haloperidol 2–5 mg IM, olanzapine 2.5–10 mg IM, or ziprasidone 10–20 mg IM) can be used to assist in calming a severely agitated patient. Agitation can be manifested as loud, physically or verbally threatening behavior, motor hyperactivity, or physical aggression. Although this technique can assist in calming an acutely agitated psychotic patient, it does not improve the extent of or time to remission, or the length of hospitalization. If haloperidol IM is used, the occurrence of EPS can eliminate some of the advantages of using an oral SGA. If the patient is receiving an antipsychotic within the usual therapeutic range, the use of lorazepam 2 mg IM as needed in combination with the maintenance antipsychotic is a rational alternative to an injectable antipsychotic. Hypotension, respiratory depression, and CNS depression are possible when injectable lorazepam and olanzapine are used concomitantly; thus this parenteral combination is not recommended.

CLINICAL CONTROVERSY

Minimal research evidence supports the use of antipsychotic doses beyond the dose range in the FDA-approved product labeling. However, clinicians frequently titrate doses above the approved range, and frequently attest to symptom improvement when this is done.

STABILIZATION THERAPY

Improvement is usually a slow but steady process over 6 to 12 weeks or longer. During the first 2 to 3 weeks, goals should include increased socialization and improvement in self-care habits and mood. Improvement in formal thought disorder should follow and can take an additional 6 to 8 weeks to respond. Patients who are early in the course of their illness can experience a more rapid resolution of symptoms than individuals who are more chronically ill. In general, if a patient has no improvement with treatment after 3 to 4 weeks at therapeutic doses, or has achieved only a partial decrease in positive and negative symptoms within 12 weeks at adequate doses, then the next algorithm stage should be considered. In more chronically ill patients, symptoms can continue to improve for 3 to 6 months. During acute stabilization, usual labeled doses of SGAs are recommended (see Table 76–5); with FGAs, a range of 300 to 1,000 mg of chlorpromazine equivalents daily is recommended.[19,25] An optimum dose of the chosen drug should be estimated in the initial treatment plan. If the patient begins to show adequate response before or at this dosage, then the patient should remain at this dosage as long as symptoms continue to improve. 7 In general, adequate time on a therapeutic antipsychotic dose is the most important factor in predicting medication response. However, if necessary, dose titration can continue within the therapeutic range every week or two as long as the patient has no side effects.

Before changing medications in a poorly responding patient, the following should be considered: Were the initial target symptoms indicative of schizophrenia or did they represent manifestations of a different diagnosis, a long-standing behavioral problem, a substance abuse disorder, or a general medical condition? Is the patient adherent with pharmacotherapy? Are the persistent symptoms poorly responsive to antipsychotics (e.g., impaired insight or judgment, or fixed delusions)? How does the patient's current status compare with response during previous exacerbations? Would this patient potentially benefit from a change to a different treatment stage (see Fig. 76–1)? Does this patient have a treatment-refractory schizophrenic illness?

The conclusion that a partially responding patient has achieved as much symptomatic improvement as possible is one that must be made with great care and after considering all possible treatment alternatives. However, treatment goals must be realistic. Medications are effective at decreasing many of the symptoms of schizophrenia (and are thus referred to as palliative), but they are not curative, and all symptoms may not abate. Although one should aim to achieve none to minimal residual positive symptoms with effective treatment, it is still unclear what a realistic goal is with regard to maximum improvement in negative symptoms.

It is important to screen patients for co-occurring mental disorders, and their presence can become more apparent during the stabilization or maintenance phases of schizophrenia treatment. Examples include substance abuse disorders, depression, obsessive-compulsive disorder, and panic disorder. As co-occurring disorders will limit symptom and functional improvement and increase the risk of relapse, it is critical that pharmacologic and nonpharmacologic

interventions for the co-occurring disorder be implemented in combination with evidence-based treatment for schizophrenia.

MAINTENANCE TREATMENT

Maintenance drug therapy prevents relapse, as shown in numerous double-blind studies. The average relapse rate after 1 year is 18% to 32% with active drug (including some nonadherent patients) versus 60% to 80% for placebo.[19,33]

After treatment of the first psychotic episode in a schizophrenic patient, medication should be continued for at least 12 months after remission.[19,32] 8 Many schizophrenia experts recommend that patients with robust medication response be treated for at least 5 years. In chronically ill individuals, continuous or lifetime pharmacotherapy is necessary in the majority of patients to prevent relapse. This should be approached with the lowest effective dose of the antipsychotic that is likely to be tolerated by the patient.[19,32]

Antipsychotics should be tapered slowly before discontinuation. Abrupt discontinuation of antipsychotics, especially low-potency FGAs and clozapine, can result in withdrawal symptoms, felt to be a manifestation of rebound cholinergic outflow. Insomnia, nightmares, headaches, gastrointestinal symptoms (e.g., abdominal cramps, stomach pain, nausea, vomiting, and diarrhea), restlessness, increased salivation, and sweating are reported. When switching from one antipsychotic to another, it is often recommended to taper and discontinue the first antipsychotic over at least 1 to 2 weeks after the second antipsychotic is initiated.[19,32] Tapering may need to occur more slowly, especially with clozapine.[19,32]

Long-Acting Injectable Antipsychotics

Long-acting antipsychotics are recommended for patients who are unreliable in taking oral medication on a daily basis, and thus are not usually used as first-line therapy. Before a long-acting antipsychotic is initiated, it should be determined whether the patient's medication nonadherence is because of side effects. If so, an alternative medication with a more favorable side-effect profile should be considered before a long-acting injectable antipsychotic.

The patient's motivation for treatment is a major factor influencing outcome. Conversion from oral therapy to a long-acting injectable is most successful in patients who have been stabilized on oral therapy. The ideal patient for a long-acting injectable is the individual who does not like the daily reminder of oral medication or is unreliable in taking medications. Paliperidone palmitate is a long-acting injectable that has the advantage of once-monthly injections and easy conversion from oral to IM treatment. It has the disadvantage of being extremely expensive.[34] A long-acting formulation of olanzapine is under FDA review at the time of publication.

Conversion from an oral antipsychotic to a long-acting medication should start with stabilization on an oral dosage form of the same agent, for a short trial (3–7 days), to determine whether the patient tolerates the medication without significant side effects. With long-acting risperidone, measurable serum concentrations are not seen until approximately 3 weeks after single-dose administration. Thus, it is important that the oral antipsychotic be administered for at least 3 weeks after beginning the injections. Dose adjustments are recommended to be made no more often than once every 4 weeks.[32,35] The recommended starting dose with risperidone long-acting injection is 25 mg, and clinical experience suggests that titration to doses greater than or equal to 37.5 mg per injection may be necessary for maintenance treatment. Long-acting risperidone has demonstrated efficacy, with an optimum dose range between 25 and 50 mg given IM every 2 weeks. Doses above 50 mg every 2 weeks are not recommended, as research indicates no greater efficacy but more EPS.[25,35]

Paliperidone palmitate can be injected into either the deltoid or the gluteal muscle, and treatment is initiated with 234 mg on day 1 and 156 mg a week later. No overlap with oral drug is necessary. Monthly IM doses are then titrated according to response within a range of 39 to 234 mg.[34]

For fluphenazine decanoate, the simplest dosing conversion method recommends 1.2 times the oral fluphenazine daily dose for stabilized patients, rounding up to the nearest 12.5-mg interval, administered in weekly doses for the first 4 to 6 weeks; or 1.6 times the oral daily dose for more acutely ill patients.[36] Subsequently, fluphenazine decanoate can be administered once every 2 to 3 weeks. Oral fluphenazine can be overlapped for 1 week. For haloperidol decanoate, a factor of 10 to 15 times the oral haloperidol daily dose is commonly recommended, rounding up to the nearest 50-mg interval, administered in a once-monthly dose with an oral haloperidol overlap for the first month. A more assertive conversion method recommends 20 times the oral daily dose, but dividing the injection into consecutive doses of 100 to 200 mg every 3 to 7 days until the entire amount is given.[37] With this method, oral medication overlap is unnecessary. The haloperidol decanoate dose is decreased by 25% at both second and third month.

Injection site reactions have been reported with the haloperidol decanoate 100 mg/mL preparation, consisting of painful pruritic swelling at the injection site.[38] Acute EPS can be seen following injections of either fluphenazine or haloperidol decanoate. These effects are minimized with the use of risperidone microspheres. Both haloperidol and fluphenazine decanoate should be administered by a deep, "Z-tract" intramuscular method. Long-acting risperidone is injected by deep IM injection in the gluteus maximus, but Z-tracting is not necessary.

Methods to Enhance Patient Adherence

It is often a challenge for individuals with chronic illnesses to maintain high levels of medication adherence, and partial compliance is a reality in the treatment of all chronic illnesses.[39] Individuals with serious mental disorders have somewhat higher nonadherence rates than those with general medical disorders, with the following explanations provided: denial of illness, lack of insight, grandiosity or paranoia, no perceived need for medication, perceived lack of input into choice of medication or dosage, side effects, misperceived "allergies," or the number of medications prescribed or doses received daily. In fact, clinicians should expect partial compliance to be the norm with regard to medication-taking behavior. This should be approached in a nonjudgmental manner, with the clinician actively engaging the patient in care and using motivational interviewing techniques as mechanisms to enhance therapeutic alliance and patient adherence.

9 Education geared toward patients becoming more informed about their illness and the effectiveness and risks of treatment can help to increase adherence.[40] These programs should be staged so that patients initially receive basic information about their disorder and its symptoms and basic information about their medication and self-monitoring techniques. As the patient is capable of dealing with more complex information, more detailed information regarding schizophrenia, psychosocial treatments, and prognosis should be discussed. Patients and families should be taught self-monitoring techniques and when to report symptom exacerbation or medication side effects to the clinician.[40] Psychoeducation strategies should include motivational interview techniques in individual counseling as well as group activities.

Recent evidence suggests that cognitive behavioral therapy focusing on medication adherence can improve patient outcome.[41] This approach is called compliance therapy. Groups facilitated by trained individuals who have the illness can be more effective in enhancing awareness and acceptance of schizophrenia and necessary treatment than groups led only by professionals. Active involvement of family members further increases the likelihood of patient adherence with treatment. In addition to programs provided by community mental health centers, support groups operated by consumer groups such as the National Alliance on Mental Illness (NAMI) are available in most urban areas. Contact information for local NAMI chapters can be accessed at *www.nami.org*. In the hospital, self-medication administration can reinforce the patient's perception of their active role in their own treatment. When patients miss outpatient appointments, active outreach interventions must be implemented to enhance patient engagement in treatment.[19,40]

MANAGEMENT OF TREATMENT-RESISTANT SCHIZOPHRENIA

In general, "treatment resistant" describes a patient who has had inadequate symptom response from multiple antipsychotic trials.[19] Traditionally, treatment resistance has been defined as lack of improvement in positive symptoms, but it can be defined by poor improvement in negative symptoms, or even by medication intolerance. Between 10% and 30% of patients receive minimal symptomatic improvement after multiple FGA monotherapy trials.[19] An additional 30% to 60% of patients have partial but inadequate improvement in symptoms or unacceptable side effects associated with antipsychotic use.[19,25] In those patients failing two or more pharmacotherapy trials, a treatment refractory evaluation should be performed to reexamine diagnosis, substance abuse, medication adherence, and psychosocial stressors. Targeted cognitive behavioral therapy or other psychosocial augmentation strategies should be considered.[25]

Clozapine

Only clozapine has shown superiority over other antipsychotics in randomized clinical trials for the management of treatment-resistant schizophrenia. Most other SGAs have either not been studied in treatment-refractory patients or evaluated in small open trials. In a seminal study, clozapine was effective in approximately 30% of patients with treatment-resistant schizophrenia, compared with only 4% treated with a combination of chlorpromazine and benztropine.[42] The criteria for treatment-resistance require two treatment failures, and includes both FGAs and SGAs. Other treatment candidates for clozapine include those patients who cannot tolerate even conservative doses of other antipsychotics.

Symptomatic improvement with clozapine in the treatment-resistant patient often occurs slowly, and as many as 60% of patients may improve if clozapine is used for up to 6 months.[32] This, in combination with clozapine's adverse-effects profile, provides sufficient information to conclude that clozapine is not a panacea for schizophrenia. Polydipsia and hyponatremia (psychogenic water drinking) is a frequent problem among treatment-resistant patients, and clozapine reportedly decreases water drinking and increases serum sodium in such patients.[43]

Because of the risk of orthostatic hypotension, clozapine is usually titrated more slowly than other antipsychotics, particularly on an outpatient basis. If a 12.5-mg test dose does not produce hypotension, then clozapine 25 mg at bedtime is recommended, increased to 25 mg twice a day after 3 days, and then increased in 25- to 50-mg/day increments every 3 days until a dose of at least 300 mg/day is reached. Because high doses are associated with significantly increased side effects, including seizures, a clozapine serum concentration is recommended before exceeding 600 mg/day. If the clozapine serum concentration is less than 350 ng/mL (350 mcg/L; 1.07 μmol/L), then the dose should be increased as side effects allow to achieve this serum concentration.[27]

Augmentation and Combination Strategies

Little empirical evidence exists to guide treatment decisions for patients who do not respond to clozapine.[25,32,27] A small number of randomized trials have examined the efficacy of clozapine augmentation with SGAs, and the results have been more negative than positive (see Fig. 76–1).[25,27] Augmentation therapy involves the addition of a nonantipsychotic drug to an antipsychotic drug in a poorly or partially responsive patient, whereas combination treatment involves using two antipsychotics simultaneously. Several guidelines should be followed regarding augmentation: (a) augmentation should be used only in inadequately responding patients; (b) augmentation agents are rarely effective for schizophrenic symptoms when used alone; (c) augmentation responders usually improve rapidly; and (d) if augmentation does not improve symptomatology, the augmenting agent should be discontinued.[32]

Mood stabilizers are frequently used as an augmentation strategy. Lithium does not enhance antipsychotic effect but may improve labile affect and agitated behavior in selected patients.[44] Valproic acid and carbamazepine have also been used. A large placebo-controlled trial supports faster symptom improvement, but no difference in maintenance treatment, when divalproex was used in combination with either olanzapine or risperidone.[45] Enzyme induction with carbamazepine can cause a decrease in antipsychotic serum concentrations and potentially worsen psychotic symptoms in some patients.[19,32] The 2009 PORT recommendations do not endorse the use of mood stabilizer augmentation in treatment resistant patients.[27]

Selective serotonin reuptake inhibitors (SSRIs), particularly fluoxetine and fluvoxamine, have reasonable evidence for improving negative symptoms when used as augmentation of FGAs. Potential benefits of combining SSRIs with SGAs require more study.[46] Consistently positive results have been reported when using SSRIs to treat obsessive-compulsive symptoms that worsen or arise during clozapine treatment.

Combining an FGA with an SGA and combining different SGAs have been suggested as intervention strategies for treatment-resistant patients. Pharmacodynamically, no rationale exists for explaining how combinations of antipsychotics would produce enhanced efficacy, and increased side effects, particularly increased EPS, metabolic effects, and hyperprolactinemia are possible results.[47] Clinically, no evidence exists to prove that antipsychotic combinations are superior to monotherapy, and the 2009 PORT recommendations do not support their use.[27] In general, a series of antipsychotic monotherapies, including clozapine, are preferred over antipsychotic combinations.[25,27,32] However, when clozapine fails to produce desired outcomes, a time-limited combination trial is sometimes recommended (see Fig. 76–1, stages 4 or 6).[19,25] Such antipsychotic combination treatment trials should be time limited (12 weeks) and the patient carefully evaluated with rating scales for changes in symptomatology. If no apparent improvement is observed, then one of the medications should be tapered and discontinued. However, if the patient has a partial response (greater than or equal to 20% improvement in positive symptoms) after 12 weeks with combination treatment in stages 4 or 6, medications should be titrated to doses at the upper end of the therapeutic range, and treatment should continue for an additional 12 weeks before a change in stage is considered.[32]

ANTIPSYCHOTIC DRUG MECHANISMS OF ACTION

The exact mechanism of action of antipsychotics is unknown. It has been suggested that antipsychotics be classified into three different categories: (a) typical or traditional (high D_2 antagonism and low 5-HT_{2A} antagonism); (b) atypical (moderate to high D_2 antagonism and high 5-HT_{2A} antagonism); and (c) atypical clozapine-like (low D_2 antagonism and high 5-HT_{2A} antagonism).[48,49] With the exception of aripiprazole, all current SGAs have a greater affinity for 5-HT_{2A} receptors than D_2 receptors.

Studies of antipsychotic receptor binding in humans have used PET scans to examine neurotransmitter receptor binding at steady-state, 12 hours post dose in small numbers of individuals. At least 60% to 65% D_2 receptor occupation is necessary to decrease positive psychotic symptoms, whereas blockade of approximately 77% or more of D_2 receptors is associated with EPS.[48,50] FGAs are dopamine receptor antagonists with high affinity for D_2 receptors. During chronic treatment with these agents, between 70% and 90% of D_2 receptors in the striatum are usually occupied. In contrast, during clozapine treatment only 38% to 47% of D_2 receptors are occupied, even with high doses. Newer SGAs have variable D_2 binding. With low-dose risperidone (2–5 mg/day), D_2 binding ranges from 60% to 79%, but with doses greater than 6 mg daily, binding commonly exceeds the 77% threshold associated with the development of EPS. Risperidone 2 mg/day produces 5-HT_{2A} binding greater than 70%, and with 4 mg/day it is nearly 100%.[48,51] Olanzapine 10 to 20 mg/day produces D_2 binding ranging from 71% to 80%, whereas at 30 to 40 mg/day, it ranges from 83% to 88%. At 5 mg/day, 5-HT_{2A} receptors are near saturation of binding.[48] Ziprasidone has the highest 5-HT_{2A}:D_2 affinity ratio of any of the currently available antipsychotics. It is also a potent 5-HT_{1A} agonist.[52]

Quetiapine has the lowest D_2 binding. At doses of 300 to 600 mg/day, D_2 binding ranges from 0% to 27%. Even at quetiapine 800 mg/day, only 30% of D_2 receptors are occupied. At these same daily doses, 45% to 90% of 5-HT_{2A} receptors are occupied. However, when quetiapine D_2 binding is examined 2 to 3 hours post dose, 58% and 64% of receptors were occupied with 400 mg and 450 mg, respectively. Transient blockade of dopamine receptors may be adequate to produce antipsychotic effect, but long-term D_2 blockade is required for production of EPS and sustained hyperprolactinemia. Low D_2 binding, and thus atypicality, can be directly associated with how rapidly the antipsychotic disassociates from the D_2 receptor.[48,51] The availability of aripiprazole, a partial agonist at D_2 receptors, represents a further elaboration of the dopamine hypothesis of antipsychotic action.[49,53] It is proposed that aripiprazole works as a functional partial agonist. Aripiprazole is a rather weak 5-HT_{2A} antagonist but a potent 5-HT_{1A} agonist.[49,53]

Iloperidone has high affinity for D_2, D_3, and 5-HT_{2A} receptors, and moderate affinity for D_4, 5-HT_6, 5-HT_7, and $\alpha_1$receptors.[54] Asenapine has high affinity for 5-HT_{2A} and D_2 receptors as well as for α_1 and histamine-1 receptors. D_2 occupancy of approximately 80% is predicted to occur with a sublingual dose of 5 to 10 mg twice daily.[55] It is clear that the SGAs differ in their mechanisms of action and most likely in the manner in which they produce an atypical clinical profile.

The primary therapeutic effects of FGAs are thought to occur in the limbic system, including the ventral striatum, whereas EPS are thought to be related to DA blockade in the dorsal striatum. 5-HT_{2A} antagonism in combination with modest D_2 blockade leads to release of dopamine in the prefrontal cortex, and this is one explanation for the decrease in negative symptoms and improvement in cognition reported with atypical antipsychotics.

Antipsychotics vary in their effects on other neurotransmitter receptor systems.[48,49,51] Although the significance of these different mechanisms on efficacy is unclear, they do potentially explain differences in side-effect profiles. These differences in pharmacodynamic profiles point out that the SGAs are not all alike, and patients obtaining an inadequate clinical response (either efficacy or side effects) with one antipsychotic may have a superior response on an alternate drug. Thus serial SGA monotherapy trials should be tried in patients receiving a suboptimal clinical response (see Fig. 76–1).

PHARMACOKINETICS

As a class, antipsychotics are highly lipophilic and highly bound to membranes and plasma proteins. They distribute readily into most tissues with a high blood supply and can accumulate in tissues; therefore they have large volumes of distribution.[56] Most antipsychotics are largely metabolized, primarily through the cytochrome P450 (CYP) pathways in the liver, except for ziprasidone, which is largely metabolized by aldehyde oxidase. Fluphenazine, perphenazine, and risperidone are metabolized through CYP2D6, and thus are susceptible to polymorphic metabolism.[57] This is also one of the major pathways for the metabolism of iloperidone.[54] Thirty percent to 35% of Africans and Asians are slow to intermediate metabolizers, and approximately 0% to 5% of African Americans, 1% of Asians, and 0% to 5% of Caucasians are poor metabolizers.[57] In addition, some populations of patients, those from Ethiopian or Swedish descent in particular, may be ultrarapid metabolizers. Polymorphism in CYP1A2 can potentially result in a decrease the metabolic rate of clozapine, and increased clozapine metabolic rate in smokers has been linked to a specific genotype.[57] The possibility of genetic polymorphism should be considered when dosing and monitoring the clinical effects of antipsychotics. Table 76–6 outlines the prominent metabolic pathways of selected antipsychotics.

Asenapine is unique in that it has less than 2% bioavailability after oral administration, but has a bioavailability of approximately 35% sublingually—the FDA approved route of administration. Eating and drinking within 10 minutes after sublingual administration will reduce bioavailability.[55]

Most antipsychotics have fairly long elimination half-lives, generally 24 hours or more, with the exception of quetiapine and ziprasidone, which have short half-lives.[53,56] Among the SGAs, only clozapine has an established therapeutic serum concentration, with efficacy being associated with a clozapine plasma concentration greater than 350 ng/mL (350 mcg/L; 1.07 μmol/L).[27] Whether a potential maximum therapeutic clozapine serum concentration exists is unknown. Clozapine serum concentration should be obtained before exceeding 600 mg daily; in patients who develop unusual or severe adverse side effects; in patients who are taking concomitant medications that can cause drug interactions; in patients who have age or pathophysiologic changes suggesting a change in pharmacokinetics; or for assessment of patient adherence.[32,33,56]

Long-acting risperidone is a suspension of drug in glycolic acid-lactate copolymer microspheres.[35] After IM injection the polymer is slowly hydrolyzed, and significant risperidone begins being released after about 3 weeks. The apparent β-phase half-life is 3 to 6 days.[35] With dosing every 2 weeks, steady-state risperidone concentrations are achieved after approximately 2 months. The apparent half-life with paliperidone palmitate after single dose administration ranges from 25 to 49 days.[34] The long-acting FGAs fluphenazine decanoate and haloperidol decanoate are esterified drugs formulated in sesame seed oil for deep intramuscular injection. Their absorption from the muscle and metabolism to the free base is sufficiently slow to cause absorption to be the rate-limiting step in determining their respective apparent half-lives.[36]

TABLE 76-6 Pharmacokinetic Parameters of Selected Antipsychotics

Drug	Bioavailability (%)	Half-Life (h)	Major Metabolic Pathways	Active Metabolites
Selected first-generation antipsychotics (FGAs)				
Chlorpromazine	10–30	8–35	FMO3, CYP3A4	7-hydroxy, others
Fluphenazine	20–50	14–24	CYP2D6	?
Fluphenazine decanoate		14.2 ± 2.2[a]days	CYP2D6	
Haloperidol	40–70	12–36	CYP1A2, CYP2D6, CYP3A4	Reduced haloperidol
Haloperidol decanoate		21 days	CYP1A2, CYP2D6, CYP3A4	Reduced haloperidol
Perphenazine	20–25	8.1–12.3	CYP2D6	7-OH-perphenazine
Second-generation antipsychotics (SGAs)				
Aripiprazole	87	48–68	CYP3A4, CYP2D6	Dehydroaripiprazole
Asenapine	<2% PO 35% SL Nonlinear	13–39	CYP1A2, UGT1A4	None known
Clozapine	12–81	11–105	CYP1A2, CYP3A4, CYP2C19	Desmethylclozapine
Iloperidone	96	18–33	CYP2D6, CYP3A4	P88
Olanzapine	80	20–70	CYP1A2, CYP3A4, FMO3	N-glucuronide; 2-OH-methyl; 4-N-oxide
Paliperidone ER	28	23	Renal unchanged (59%) Multiple pathways	None known
Paliperidone Palmitate		25–49 days	Renal unchanged (59%)Multiple pathways	None known
Quetiapine	9 ± 4	6.88	CYP3A4	7-OH-quetiapine
Risperidone	68	3–24	CYP2D6	9-OH-risperidone
Risperidone Consta		3–6 days	CYP2D6	9-OH-risperidone
Ziprasidone	59	4–10	Aldehyde oxidase, CYP3A4	None

[a]Based on multiple dose data. Single dose data indicate a β-half-life of 6–10 days.

Data from Citrome,[34,54,55] Harrison and Goa,[35] Ereshefsky et al.,[36,37] DeLeon et al.,[53] Mauri et al.,[56] Zhou, et al.,[57] Spina and de Leon.[111] and Urichuk, et al.[112]

ADVERSE EFFECTS

Table 76–7 presents the relative incidence of common categories of antipsychotic side effects. Side effects are discussed below with respect to organ system affected. A general approach to monitoring and assessing side effects requires prospective monitoring by clinicians, preferably using a thorough review of systems approach. Patient-oriented self-rated side-effect scales can be helpful, as many patients with schizophrenia do not readily complain of side effects.

With the variety of antipsychotics currently available, using an alternative medication should be considered in patients who complain of poorly tolerated side effects. Because medication side effects are one of the primary predictors of patient nonadherence, the clinician should take advantage of the treatment options currently available in an attempt to improve patient outcomes. As new antipsychotics become available, side effects and risks associated with different drugs should be reevaluated. As we learn more about relative side-effect risks (e.g., weight gain, glucose intolerance, QTc prolongation, acute EPS, and tardive dyskinesia), it will be necessary to regularly reconsider which antipsychotics should be considered first-line treatment alternatives.

Endocrine System

DA blockade in the tuberoinfundibular tract results in increased prolactin levels as DA is the major prolactin-inhibiting factor. Hyperprolactinemia may occur in up to 87% of patients treated with FGAs, risperidone or paliperidone. The major side effects associated with hyperprolactinemia are gynecomastia, galactorrhea, menstrual irregularities, decreased libido, and sexual dysfunction. Although not conclusive, chronic hyperprolactinemia has been associated with decreased bone density. Tolerance does

TABLE 76-7 Relative Side-Effect Incidence of Commonly Used Antipsychotics[a,b]

	Sedation	EPS	Anticholinergic	Orthostasis	Weight Gain	Prolactin
Aripiprazole	+	+	+	+	+	+

[b]Individual patient risk varies depending on patient-specific factors.

not appear to develop to antipsychotic induced hyperprolactinemia. Switching to aripiprazole or ziprasidone, which have minimal sustained effect on prolactin, is the most reasonable treatment option.[58]

Weight gain is frequently reported in both adults and children receiving antipsychotics.[58,59] Although the exact mechanism is uncertain, weight gain has been associated with antihistaminic effects, antimuscarinic effects, and blockade of 5-HT_{2C} receptors including 5-HT_{2c} receptor polymorphism. However, dietary factors and activity levels can play a significant role in this population, as does renourishment after a period of poor self-care. In particular, significant weight gain, as defined by greater than or equal to 7% of the baseline body weight, after 1 year of treatment has been seen in as many as is 80% of patients treated with olanzapine, 58% treated with risperidone, and 50% treated with quetiapine.[58] The risk of weight gain may be greater in patients with their first psychotic episode. Ziprasidone and aripiprazole both have been associated with minimal weight gain.

The clinical significance of weight gain during antipsychotic therapy is substantial. The risk of cardiovascular-related mortality is higher in individuals with schizophrenia,[58,60] and this is further aggravated by drug-related weight gain and the high prevalence of smoking. Additionally, obesity is a risk factor for diabetes mellitus.[58] Weight gain during treatment is a major reason for poor patient medication adherence, and patients commonly report weight gain as being a concern.[61]

Several different genetic variations have been correlated with predisposition for antipsychotic-associated weight gain. Recent meta-analysis of all genetic studies looking at the −759 C/T promoter region polymorphism of the 5-HT_{2C} receptor gene confirmed an association of 5-HT_{2C} in antipsychotic-induced weight gain.[62] Polymorphisms in leptin and leptin receptor genes have also been linked with clozapine and olanzapine-associated weight gain.[63,64] Alfa-2a-adrenergic receptor gene, G protein beta-3 subunit gene, and brain-derived neurotrophic factor (BDNF) gene have been genetic targets; however, results are inconsistent as to whether a relationship exists with these polymorphisms and antipsychotic-associated weight gain.[65–67]

A number of pharmacologic interventions have been attempted for antipsychotic-related weight gain, but in general these should be discouraged. Switching patients to antipsychotics less likely to cause weight gain, dietary restriction, exercise, and behavior modification programs are reported to be successful in small short-term studies.[68] An American Diabetes Association consensus task force recommends consideration of a change in antipsychotic if a patient gains more than 5% of baseline body weight after starting the drug.[69]

Schizophrenic patients have a higher prevalence of type 2 diabetes than the nonschizophrenic population. Beyond this, antipsychotics may adversely affect glucose levels in diabetic patients. The extent to which these effects are related to drug-induced weight increase is unclear.[58,69] Data collected from the FDA MedWatch Drug Surveillance System for clozapine, olanzapine, quetiapine, and risperidone indicate that nearly 60% of the new-onset diabetes reported occurred within the first 6 months of treatment initiation.[58,69] Olanzapine has the highest risk of new-onset diabetes followed by risperidone and then quetiapine. Although likely less than with the other SGAs, inadequate data are available to accurately estimate the risk with ziprasidone and aripiprazole.[58] Clozapine likely poses a risk at least as great as with olanzapine. The 2009 PORT recommendations do not recommend olanzapine as a first line antipsychotic option.[27] In March 2004, the FDA issued a safety alert requiring revisions in the labeling of all SGAs that describes the increased risk of diabetes mellitus in patients taking atypical antipsychotics.[70] Given the public health significance of diabetes, clarifying the diabetogenic effect of SGAs is a major focus of current research. Moreover, designing care models and standards for managing diabetes in patients with schizophrenia is another major consideration.

CLINICAL CONTROVERSY

The relative risk of diabetes mellitus versus the risk of EPS associated with different antipsychotics makes individual antipsychotic choice challenging. This is particularly true given that olanzapine causes the most weight gain and appears to have the highest risk of precipitating diabetes mellitus (except for clozapine), but yet research does show some modest benefits with regard to efficacy.

Cardiovascular System

Orthostatic Hypotension Postural or orthostatic hypotension, defined as a greater than 20-mm Hg drop in systolic pressure, is caused by α-adrenergic blockade, and may occur in up top 75% of treated patients.[71] Antipsychotics with a greater risk should have their doses titrated over several days to decrease the risk of symptomatic hypotension. Antipsychotic combination treatment may result in a greater risk of orthostasis.[71] Orthostatic hypotension can occur in any patient, but diabetic patients with preexisting cardiovascular disease and the elderly seem particularly predisposed. Patients should be advised to slowly move to the standing position to allow for adaptation. Tolerance to this effect may occur within 2 to 3 months. If not, lower doses or a change to an antipsychotic with less α-blockade can be attempted.

Electrocardiographic Changes Among the antipsychotics, thioridazine, clozapine, iloperidone, and ziprasidone are most likely to cause electrocardiogram (ECG) changes. ECG changes include increased heart rate (through sinus tachycardia from anticholinergic effects, or reflex tachycardia from α-adrenergic blockade), flattened T waves, ST segment depression, and prolongation of QT and PR intervals. The most clinically important of these potential changes is prolongation of the QTc, which has been associated with ventricular arrhythmias, including torsades de pointes syndrome. Thioridazine has been shown to prolong the QTc on average approximately 20 milliseconds (msec) longer than haloperidol, risperidone, olanzapine, or quetiapine.[72] Thioridazine's effects on QTc prolongation is dose related, and has led to a black box warning in the FDA-approved product labeling. In the same study, ziprasidone prolonged the QTc approximately 10 msec longer or about one-half of the effect of thioridazine.[71] Widespread clinical use suggests that ziprasidone's effects on the ECG are not associated with clinical sequelae, unless the patient has baseline risk factors.[71] Iloperidone has a dose-related effect on QTc, with an average prolongation of about 9 msec at a dose of 20 to 24 mg/day.[54] Although the precise point at which QTc prolongation becomes clinically dangerous is unclear, it has been recommended to discontinue a medication associated with QTc prolongation if the interval consistently exceeds 500 msec.

Greater caution regarding antipsychotic choice and use is necessary in the elderly, in patients with preexisting cardiac or cerebrovascular disease, and in patients taking diuretics or medications that may prolong the QTc.[71] In patients older than 50 years of age, a pretreatment ECG is recommended, as are baseline serum potassium and magnesium levels. These factors should be considered in antipsychotic selection.

Sudden Cardiac Death A recent, large retrospective analysis found risk of sudden cardiac death with current use of FGAs and SGAs was twice that of nonusers of antipsychotics,[73,71] with risk increasing with escalated dose. Further meta-analysis has conferred a lack of evidence for differential effects on cardiovascular mortality favoring one class of antipsychotics over the other.[71,73] Further prospectively designed studies are needed to confirm a dose-dependent increase in cardiovascular sudden death with current antipsychotic use, and also to determine whether certain antipsychotics are associated with a greater risk than others.

Lipid Changes

Treatment with at least some SGAs and phenothiazines appears associated with elevations in serum triglycerides and cholesterol. Oxidation of apolipoprotein B lipoproteins and elevations in sterol regulatory element binding protein-controlled gene expression, are among the purported mechanisms by which these lipid changes occur during antipsychotic treatment.[74,75] Among the SGAs, less risk for change in serum lipid or cholesterol levels can occur with risperidone, ziprasidone, or aripiprazole.[58,60] In the CATIE trial, olanzapine was associated with greater and significant adverse effects on metabolic parameters, including lipids, blood glucose, and body weight versus the other study treatments, but these differences in tolerability did not affect discontinuation rates.[76]

The occurrence of weight gain, diabetes, and lipid abnormalities during antipsychotic therapy is consistent with the development of metabolic syndrome (i.e., syndrome X). Cohorts of patients with schizophrenia have shown elevated prevalence of metabolic syndrome as compared with general population cohorts. Prevalence rates of metabolic syndrome in U.S. populations range from 28% to 60%, with 40.9% reported in the prospectively designed CATIE trial.[77]

Metabolic syndrome consists of raised triglycerides (greater than or equal to 150 mg/dL [170 mmol/L]), low HDL cholesterol (less than or equal to 40 mg/dL [103 mmol/L] for males, l less than or equal to 50 mg/dL [1.29 mmol/L] for females), elevated fasting glucose (greater than or equal to 100 mg/dL [5.6 mmol/L]), blood pressure elevation (greater than or equal to 130/85 mm Hg), and weight gain (abdominal circumference greater than 102 cm [40 in] for males, greater than 88 cm [34 in] in females).[58,60] These abnormalities dictate an important role for general health screening and monitoring in patients with schizophrenia, and prompt intervention when such abnormalities occur. The propensity of individual antipsychotics to produce metabolic disturbances should be considered in the context of individual patient risk factors at the time of drug selection.

Autonomic Nervous System

Patients receiving antipsychotics or antipsychotics in combination with anticholinergics, can experience anticholinergic side effects (e.g., dry mouth, constipation, tachycardia, blurred vision, inhibition or impairment of ejaculation, urinary retention, or impaired memory). This is particularly so with low-potency FGAs, and the elderly are especially sensitive to these effects. Of the SGAs, clozapine and olanzapine have moderately high rates of causing anticholinergic effects. Constipation, caused by slowed peristaltic movement and decreased intestinal fluid content, should be closely monitored and treated, especially in the elderly. Paralytic ileus and necrotizing enterocolitis can also occur.

Central Nervous System

Extrapyramidal System

Dystonia. Dystonia is a state of abnormal tonicity, sometimes described simplistically as a severe "muscle spasm."[78,79] More accurately, they are prolonged tonic contractions, with a rapid onset, usually within 24 to 96 hours of dosage initiation or dosage increase. They can be life-threatening, as in the case of pharyngeal-laryngeal dystonias, and can contribute to patient nonadherence. Types of dystonic reactions include trismus, glossospasm, tongue protrusion, pharyngeal-laryngeal dystonia, blepharospasm, oculogyric crisis, torticollis, and retrocollis. Dystonic reactions occur primarily with FGAs. Risk factors include younger patients (especially males), the use of high-potency agents, and high dosage. The overall incidence from the 1960s through the mid-1970s ranged from 2.3% to 10%, but as higher-potency traditional antipsychotics became more widely used, the rate increased to as high as 64%.

TABLE 76-8 Agents Used to Treat Extrapyramidal Side Effects

Generic Name	Equivalent Dose (mg)	Daily Dosage Range (mg)
Antimuscarinics		
Benztropine[a]	1	1–8[b]
Biperiden[a]	2	2–8
Trihexyphenidyl	2	2–15
Antihistaminic		
Diphenhydramine[a]	50	50–400
Dopamine agonist		
Amantadine	NA	100–400
Benzodiazepines		
Lorazepam[a]	NA	1–8
Diazepam	NA	2–20
Clonazepam	NA	2–8
β-Blockers		
Propranolol	NA	20–160

NA, not applicable
[a]Injectable dosage form can be given intramuscularly for relief of acute dystonia.
[b]Dosage can be titrated to 12 mg/day with careful monitoring; nonlinear pharmacokinetics have been reported.

Intramuscular or intravenous anticholinergics (Table 76–8) or benzodiazepines are the treatments of choice for dystonia. Benztropine mesylate 2 mg or diphenhydramine 50 mg can be given intramuscularly or intravenously. Diazepam 5 to 10 mg by slow IV push or lorazepam 1 to 2 mg intramuscularly are treatment alternatives. Relief is typically seen within 15 to 20 minutes of an intramuscular injection and within 5 minutes of intravenous administration. The antipsychotic can be continued, with concomitant short-term use of oral anticholinergic agents. In general, prophylactic anticholinergic medications are not recommended routinely with all FGAs. However, prophylaxis is reasonable when using high-potency FGAs (e.g., haloperidol or fluphenazine) in young men, and in patients with a history of dystonia.[80] Dystonias can also be minimized by the use of lower initial FGA doses. Anticholinergics are good choices for prophylaxis, whereas amantadine has not been proven effective for this purpose. The risk of dystonia is greatly reduced with SGAs.

Akathisia. Akathisia is defined as the inability to sit still and as being functionally motor restless. The most accurate diagnosis is made by combining subjective complaints with objective symptoms (pacing, shifting, shuffling, or tapping feet). Subjectively, patients may describe a feeling of inner restlessness or disquiet or a compulsion to move or remain in constant motion. Akathisia occurs in 20% to 40% of patients treated with high-potency FGAs.[79,80] Akathisia is frequently accompanied by dysphoria.

Akathisia responds poorly to anticholinergics.[79,80] Traditionally, reduction in antipsychotic dosage has been considered the best intervention; however, this might not be a realistic goal in an acutely psychotic patient. A logical alternative is to switch to an antipsychotic with a lower risk of akathisia, or an antipsychotic previously used in the patient without adverse effect. Akathisia can occasionally occur with SGAs. Quetiapine and clozapine appear to have the lowest risk of producing akathisia.[79,80]

Benzodiazepines have been used for treatment of akathisia, but the high prevalence of co-occurring substance abuse in schizophrenia discourages their prescribing.[80] The β-blockers (e.g., propranolol in doses up to 160 mg daily, nadolol in doses up to 80 mg daily, and metoprolol in β_2-selective doses of 100 mg daily or less) are reported as effective.[80]

Pseudoparkinsonism. Pseudoparkinsonism, produced by D_2 blockade in the nigrostriatum, resembles idiopathic Parkinson disease. A patient with pseudoparkinsonism can present with any of four cardinal symptoms: (1) akinesia, bradykinesia, or decreased motor activity including difficulty initiating movement, as well as extreme slowness, mask-like facial expression, micrographia, slowed speech, and decreased arm swing; (2) tremor, known as pill-rolling type, that is predominant at rest and decreases with movement, usually involving the fingers and hands, although tremors can also be seen in the arms, legs, neck, head, and chin; (3) cogwheel rigidity, seen as the patient's limbs yielding in jerky, ratchet-like fashion when passively moved by the examiner; and (4) postural abnormalities and instability manifested as stooped posture, difficulty in maintaining stability when changing body position, and a gait that ranges from slow and shuffling to festinating. Fatigue and weakness can be noted, as well as oral abnormalities including dysphagia, dysarthria, and abnormal palmomental and glabellar reflexes. The overall incidence of pseudoparkinsonism from FGAs ranges from 15.4% to 36%, depending on the drug and dose. Akinesia alone can be seen in 59% of patients on high-potency FGAs. Other risk factors include increasing age and possibly female gender. The onset of symptoms is typically 1 to 2 weeks after initiation of antipsychotic therapy or a dose increase.

The efficacy of anticholinergic medications in treating symptoms of pseudoparkinsonism is well established.[79,80] Benztropine's long half-life allows once- to twice-daily dosing. Typical dosing is 1 to 2 mg twice a day up to a usual maximum dosage of 8 mg daily, although some patients will continue to respond to doses up to 12 mg. Trihexyphenidyl (2–5 mg 3 times a day), diphenhydramine (25–50 mg 3 times a day), and biperiden (2 mg 3 times a day) usually require thrice-daily administration. Diphenhydramine produces more sedation than the other agents. All of the anticholinergics have been abused for their euphoriant effects.[78] Symptoms typically begin to resolve within 3 to 4 days after initiation of treatment, but a minimum of at least 2 weeks of treatment is normally required for full response. Amantadine is generally as efficacious for pseudoparkinsonism as anticholinergics, with significantly less effect on memory function.[80] The need for prophylactic use of these agents against pseudoparkinsonism is less convincing than with dystonias, and is unnecessary when using SGAs.[80] The long-term treatment of pseudoparkinsonism with antiparkinsonism medication is somewhat controversial, and an attempt should be made to taper and discontinue these agents 6 weeks to 3 months after symptom resolution. If symptoms reappear, then switching to an SGA should be considered. The risk of pseudoparkinsonism with SGAs is low. When risperidone is used in doses greater than 6 mg/day, the risk of pseudoparkinsonism symptoms approaches that with FGAs. Quetiapine, aripiprazole, or clozapine are reasonable alternatives in a patient experiencing extrapyramidal side effects with other SGAs.[32,53,79,80]

Tardive Dyskinesia. Tardive dyskinesia is a syndrome characterized by abnormal involuntary movements occurring late in onset in relation to initiation of antipsychotic therapy. Tardive dyskinesia is sometimes irreversible and continues to be a controversial issue.

The classic description of tardive dyskinesia is the buccal-lingualmasticatory (BLM) syndrome, or orofacial movements. The onset of BLM movements is usually insidious. Typically, they are the first detectable signs of tardive dyskinesia and begin with mild forward, backward, or lateral movements of the tongue. As the disorder progresses, more obvious or frank BLM movements appear, including tongue thrusting, rolling, or fly-catching movements, and chewing or lateral jaw movements. Tardive dyskinesia symptoms can interfere with the patient's ability to chew, speak, or swallow. Further complications include oral ulcerations, inability to wear dentures, and inflammation and loosening of mandibular joints. Eating difficulties and malnutrition can be severe complications. Weight loss can be seen in patients with esophageal or respiratory manifestations but not in those with truncal movements. Facial movements include frequent blinking, brow arching, grimacing, upward deviation of the eyes, and lip smacking. Involvement of the extremities sometimes occurs, with the appearance of restless choreiform and distal athetosis of limbs including twisting, spreading, flexion and extension of fingers, toe tapping, and toe dorsiflexion. Unusual posture, hyperextension, pelvic thrusting, axial hyperkinesia ballismus, exaggerated lordosis, rocking, and swaying are occasionally observed. Among the differential diagnoses are withdrawal dyskinesias occurring after short-term use of antipsychotics, spontaneous orofacial dyskinesias in the elderly, orofacial dyskinesias in the edentulous, stereotypic movements in schizophrenics, Huntington disease, and congenital torsion dystonia. Orofacial movements are more common in older patients, whereas the truncal axial movements are classically reported in young adults. Movements can worsen with stress, decrease with sedation, and disappear during sleep. Concentration on motor tasks or attempts to suppress the movements can actually increase them.

Early signs of tardive dyskinesia can be reversible but if allowed to persist they can become irreversible, even with drug discontinuation. When the antipsychotic dose is decreased or tapered and discontinued, worsening of abnormal movements can occur, followed by possible slow improvement after months or years if the patient remains on lower doses or discontinues treatment. No standardized diagnostic criteria for tardive dyskinesia are available. Abnormal involuntary movements can be detected early through physical assessment and the use of rating scales. Available rating scales include the Abnormal Involuntary Movements Scale (AIMS) and the Dyskinesia Identification System: Condensed User Scale (DISCUS).[32,81] Neither scale is diagnostic in itself.

Risk factors include increasing age, the occurrence of acute EPS, poor antipsychotic drug response, diagnosis of organic mental disorder, diabetes mellitus, mood disorders, and possibly female gender.[78,79] Duration of antipsychotic therapy, daily dosage, and possibly total cumulative dosage are probably the most significant risk factors. Polymorphisms of the dopamine D_3 receptor, 5-HT_{2C} receptor, and the superoxide dismutase-2 genes have all been implicated in varying the risk of TD with antipsychotic use.[82] Overall morbidity and mortality are greater in tardive dyskinesia patients.

With FGAs, the reported incidence of tardive dyskinesia ranges from 0.5% to 62%.[78,79] In a first episode of schizophrenia, the incidence is estimated at about 5% per year, with the overall prevalence ranging from 20% to 25% with long-term treatment. Among the elderly, the overall risk of tardive dyskinesia is higher.[78] Tardive dyskinesia is not always permanent, with remission of symptoms observed in 25% of patients after 5 years of continued treatment.[78]

The risk of tardive dyskinesia with SGAs is significantly lower.[79] A systematic review of 11 studies with SGAs lasting 1 year or more found an overall risk of tardive dyskinesia to be approximately 0.8% per year in nonelderly (<65 years) adults and 5.3% per year in the elderly (≥65 years). For individual agents, the annual incidence rates ranged from zero to 0.5% for olanzapine to 0.6% to 0.7% for risperidone or quetiapine. To date, there are no reports of tardive dyskinesia with clozapine monotherapy.

Prevention of tardive dyskinesia is important, as treatment of the movements once they occur is difficult. One of the more compelling

arguments for the first-line use of SGAs is their lower risk of tardive dyskinesia.[25,32,83] (see Fig. 76–1). Regular neurologic examinations (AIMS or other scales) should be performed at baseline and at least quarterly to assess for early signs of tardive dyskinesia. At the first signs of tardive dyskinesia, the need for continuing antipsychotic treatment should be reassessed. In such situations, if the patient is taking an FGA and continuing treatment is indicated, the medication should be switched to an SGA.

Numerous drugs have been used in an attempt to treat tardive dyskinesia. In two controlled trials lasting 22 to 52 weeks, clozapine decreased abnormal involuntary movements.[78,84] Switching antipsychotic therapy to clozapine is a favored first-line pharmacotherapeutic strategy, particularly in patients with moderate to severe dyskinesias.[78,79,84]

Sedation and Cognition Chlorpromazine, thioridazine, mesoridazine, clozapine, olanzapine, and quetiapine are the most sedating antipsychotics. Administration of most or all of the daily dosage at bedtime can decrease daytime sedation and in some patients eliminate the need for hypnotic agents. Sedation occurs early in treatment and can decrease over time.[32] Oversedation can play a large role in cognitive, perceptual, and motor dysfunction. However, positive effects of medication on cognition are seen with chronic administration, evidenced by improvements in tasks involving visual-motor skills, attention to task, and working memory. Compared with FGAs, several studies have shown cognitive benefits of SGAs. However, results from the CATIE trial showed no differences in cognitive improvement between SGAs and the FGA perphenazine.[85] Comparative effects of different SGAs on cognition are as yet unclear, but available studies suggest that different SGAs can have effects on varying cognitive domains.[86] An algorithm-driven disease management program was shown to improve cognition over a 9-month period.[87]

Seizures An increased risk of drug-induced seizures occurs in all patients treated with antipsychotics. However, this risk is greater if the following predisposing factors are present: preexisting seizure disorder, history of drug-induced seizure, abnormal electroencephalogram (EEG), and preexisting CNS pathology or head trauma. Seizures are more closely associated with the use of higher doses, rapid dosage increases, and on initiation of treatment. When an isolated seizure occurs, a dosage decrease is first recommended; anticonvulsant therapy is not recommended. Although spontaneously occurring seizures have been reported with most antipsychotics, the highest potential risk for an antipsychotic-related seizure is with clozapine or chlorpromazine. If a change in antipsychotic therapy is required because of a drug-induced seizure, risperidone, molindone, thioridazine, haloperidol, pimozide, trifluoperazine, and fluphenazine are associated with the lowest potential.[80]

Thermoregulation Poikilothermia, the body temperature adjusting to the ambient temperature, can be a serious side effect of antipsychotic therapy in temperature extremes.[88] Hyperpyrexia can be a danger in hot weather or during exercise. Inhibition of sweating, a result of anticholinergic properties impairing the peripheral mechanisms of heat dissipation, can also contribute to this problem, which in its severest form can lead to heat stroke. Hypothermia is also a risk, particularly in the elderly (≥65 years) and in cold climates. All patients receiving antipsychotics should be educated about these potential problems. Thermoregulatory problems are reportedly more common with the use of low-potency FGAs and can occur with the more anticholinergic SGAs.

Neuroleptic Malignant Syndrome Neuroleptic malignant syndrome (NMS) occurs in 0.5% to 1% of patients receiving FGAs. The rate of NMS has diminished since the introduction of SGAs, and reliable current estimates of the incidence with SGAs are not available. NMS can occur more frequently in patients receiving high-potency FGAs, injectable or depot FGAs, and in patients who are dehydrated, with physical exhaustion, or organic mental disorders. Although less common, NMS has been reported with SGAs, including clozapine. The onset of symptoms varies from early in treatment to months later. It develops rapidly, over the course of 24 to 72 hours. NMS can occur after antipsychotic discontinuation, especially when depot agents are used. Possible mechanisms of NMS include disruption of the central thermoregulatory process or excess production of heat secondary to skeletal muscle contractions. The differential diagnosis includes heat stroke, lethal catatonia, anesthetic-associated malignant hyperthermia, anticholinergic toxicity, and monoamine oxidase inhibitor drug interactions. Cardinal signs and symptoms of NMS are body temperature exceeding 38°C (100.4°F), altered level of consciousness, autonomic dysfunction (tachycardia, labile blood pressure, diaphoresis, tachypnea, or urinary or fecal incontinence), and rigidity. Laboratory evaluation, although nonspecific, frequently shows leukocytosis with or without a left shift, increases in creatine kinase (CK), aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and myoglobinuria.[80]

Treatment should begin with antipsychotic discontinuation and supportive care. In many cases that alone is effective. The role of adjunctive agents is unclear, yet they are often used. The DA agonist bromocriptine reduces rigidity, fever, or CK in up to 94% of patients, whereas the use amantadine has been successful in up to 63% of patients. Dantrolene has been used as a skeletal muscle relaxant, with effects on temperature, heart rate, respiratory rate, and CK in up to 81% of patients.[80] Wide recognition and rapid antipsychotic discontinuation has drastically reduced mortality from 20% 25 years ago to 4% in the mid-1990s.

Many patients with schizophrenia, despite having had NMS, will require future antipsychotic pharmacotherapy. A review of antipsychotic rechallenges suggests that the risk of rechallenge is acceptable in most patients, provided that the patient is observed for an extended period of time (2 weeks or more is suggested) without antipsychotics, that there is careful monitoring and slow dose titration, and that the patient is maintained on the lowest possible dose.[80] A different antipsychotic, a SGA or a low potency FGA, should be used for rechallenge following an episode of NMS.

Psychiatric Side Effects Antipsychotic-induced akathisia, akinesia, and dysphoria can have unfortunate sequelae, resulting in what has been termed "behavioral toxicity."[30] Akinesia, characterized by "diminished spontaneity," results in symptoms of apathy and withdrawal, often mistaken for the negative symptoms of schizophrenia; these patients can actually appear depressed. Delirium and psychosis are reported with larger doses of FGAs or combinations of anticholinergics with FGAs. Chronic confusion and disorientation can occur in the elderly as a result of antipsychotic treatment.[89] Unfortunately, the link is not always made with antipsychotic therapy, and the patient is misdiagnosed with an delirium from a different etiology. This clinical presentation, called a *pseudodementia*, may be reversible on discontinuation of the antipsychotic.

Ophthalmologic Effects Anticholinergic effects of antipsychotics or concomitant antiparkinson medications can exacerbate narrow-angle (angle closure) glaucoma. Antipsychotics with low anticholinergic effects should be used in such individuals, and they should be appropriately monitored.[90]

Opaque deposits in the cornea and lens occur with chronic phenothiazine treatment, most frequently with chlorpromazine. Although visual acuity is not usually affected, periodic slit-lamp ophthalmologic examinations are frequently recommended in patients receiving long-term treatment with phenothiazines, as fully formed cataracts are a possibility.[90]

Because of cataract development and lenticular changes in animals, baseline and periodic eye examinations are recommended in the product labeling for quetiapine.[91] However, clinical use of quetiapine since marketing has not shown a significant risk of cataracts.[32,91] Retinitis pigmentosa can result from use of thioridazine doses greater than 800 mg daily. It is caused by melanin deposits and can result in permanent visual impairment or blindness.

Genitourinary System

Urinary hesitancy and retention is reported with low-potency FGAs and with clozapine. Anticholinergic effects cause smooth muscle slowing and paralyze the detrusor muscle of the bladder, requiring greater urine volume to evoke muscle contraction. Men with benign prostatic hypertrophy are especially prone to this effect.[92]

Urinary incontinence is thought to be caused by α-blockade, and among the SGAs, it appears to be particularly problematic with clozapine. The incidence has been reported to be as high as 44%, and it can be persistent in 25% of patients.[93]

Numerous mechanisms may result in sexual dysfunction, including dopaminergic blockade, hyperprolactinemia, histaminergic blockade (sedation), anticholinergic effects, and α-adrenergic blockade. Although inadequately studied, multiple mechanisms are likely responsible for sexual dysfunction. Unmedicated individuals with schizophrenia report decreased libido. Most but not all studies show a relationship between hyperprolactinemia and sexual dysfunction, including decreased libido, erectile dysfunction, difficulty achieving orgasm, and ejaculatory abnormalities. Although risperidone produces at least as much sexual dysfunction as FGAs, other SGAs, which have weak effects on prolactin, produce less sexual dysfunction. It is unclear whether hyperprolactinemia directly impairs sexual functioning, reflects high dopaminergic blockade from risperidone and FGAs, or is associated with other mechanisms of producing sexual dysfunction. Patients experiencing sexual dysfunction with FGAs or risperidone should be switched to an SGA with less effect on prolactin.[94]

Hematologic System

Transient leukopenia can occur during initial treatment with antipsychotics; however, it typically does not progress to clinically significant parameters.[95] The three antipsychotics with highest relative risk of neutropenic are in rank order clozapine, chlorpromazine, and olanzapine.[96] If the WBC count is less than 3,000/mm^3 (3×10^9/L), or if the absolute neutrophil count (ANC) is less than 1,000/mm^3 (1×10^9/L), the antipsychotic should be discontinued, and the WBC monitored closely until it returns to normal. Agranulocytosis reportedly occurs in 0.01% of patients receiving FGAs, and more frequently with chlorpromazine and thioridazine. The onset is usually within the first 8 weeks of therapy. Agranulocytosis can initially manifest as a local infection, with sore throat, leukoplakia, erythema, and ulcerations of the pharynx. These symptoms in any patient receiving antipsychotics should signal the immediate need for a WBC count. If either the WBC count or ANC falls below these parameters, the drug should be discontinued immediately and the patient monitored closely for the development of secondary infections. Isolated rare cases of thrombocytopenia and eosinophilia have been reported.

Agranulocytosis with clozapine significantly limits the usefulness of this agent. Data reveal that the risk of developing neutropenia or agranulocytosis with clozapine is approximately 3% and 0.8%, respectively.[96] Increasing age and female gender are associated with greater risk. The time period for greatest risk is between months 1 and 6 of treatment, and weekly WBC monitoring for the first 6 months of therapy is mandated in the FDA-approved product labeling. After the first 6 months, the labeling allows the frequency of WBC monitoring to be decreased to every 2 weeks for months 7 through 12, after which it can be decreased to monthly if all WBCs are normal. If the total WBC count drops to less than 2,000/mm^3 (2×10^9/L), or the ANC is less than 1,000/mm^3 (1×10^9/L), clozapine should be discontinued and the patient monitored closely. Granulocyte colony-stimulating factor filgrastim has been used in hope of hastening resolution or decreasing morbidity. In cases of moderate neutropenia (granulocytes 2,000–3,000/mm^3 [2×10^9/L to 3×10^9/L], or ANC 1,000–1,500/mm^3 [1×10^9/L to 1.5×10^9/L]), which occurs in up to 2% of patients, clozapine should be discontinued with daily monitoring of complete blood counts until values return to normal.

Dermatologic System

Allergic reactions are rare and usually occur within 8 weeks of initiating therapy, manifesting as maculopapular, erythematous, pruritic rashes that are evident on the face, neck, trunk, or extremities. Contact dermatitis, including the oral mucosa, can occur in patients or medical personnel. For patients, mixing the antipsychotic concentrate in a sufficient quantity of a nonacidic liquid and swallowing it quickly decreases problems in susceptible patients. Care should be taken in the handling and preparation of liquid FGAs.

Phenothiazine can absorb ultraviolet light, resulting in the formation of free radicals, which can have damaging effects on the skin. Both SGAs and FGAs cause photosensitivity. Erythema and severe sunburns can occur. Exposure to sunlight should be limited, and patients should be educated about the use of a maximally blocking sunscreen, hats, protective clothing, and sunglasses.[97,98]

Blue-gray or purplish skin coloration in areas exposed to sunlight occurs in patients receiving higher doses of low-potency phenothiazines during long-term administration, especially with chlorpromazine. It commonly occurs with concurrent corneal or lens pigmentation.

Miscellaneous Adverse Effects

A sometimes troubling side effect with clozapine is sialorrhea, which can occur in up to 54% of patients. The mechanism of clozapine-induced drooling is unclear. Although both anticholinergics and α-agonists have been used to treat clozapine related sialorrhea, research evidence is insufficient to make specific recommendations.[99]

TOXICITY WITH OVERDOSE

Acute overdose with antipsychotics rarely results in serious symptomatology. Mild intoxication manifests as sedation, hypotension, and miosis, whereas with severe intoxication, agitation and delirium can typically progress to motor retardation, seizures, cardiac arrhythmias, respiratory arrest, and coma. Dystonias and pseudoparkinsonism symptoms also occur. Supportive measures, gastric lavage, and activated charcoal are recommended. Induction of emesis can be difficult because of effects on the chemoreceptor trigger zone, and dialysis is ineffective because of the degree of drug-protein binding. Phenytoin or sodium bicarbonate are useful in the treatment of quinidine-like cardiac conduction effects on the QRS or QTc. Physostigmine is not generally recommended to reverse anticholinergic toxicity because of deleterious effects on arrhythmias and seizure threshold.[98]

USE IN PREGNANCY AND LACTATION

Minimal data exist regarding the effects of pregnancy on schizophrenia. However, disorganized thought processes, impaired cognition, and negative symptoms can have a detrimental effect on the functioning and self-care of the mother, and therefore

adversely affect the fetus.[100] Currently available data assessing the risk of teratogenesis with antipsychotic agents are insufficient. Epidemiologic studies show a slightly increased risk of birth defects with low-potency FGAs. Haloperidol is the best studied of all antipsychotics, and no relationship between its use and teratogenicity has been found. A recent study has shown a greater than 2-fold elevated risk of preterm birth in women with schizophrenia taking FGAs as compared with unaffected mothers not taking antipsychotics.[101]

SGAs have increasing information available regarding safety in pregnancy; however, very few large studies and very few prospective studies have been performed to evaluate possible teratogenicity of SGAs. Definitive data are still lacking. Two prospectively designed nonrandomized, observational studies have reported no increased risk of teratogenic birth defects with SGA exposure.[102,103] One large registry data study performed in Sweden found a significant increased risk of cardiovascular defects with FGA or SGA exposure;[104] however, when stratifying by antipsychotic class, it was found that all defects were found in those exposed to FGAs, while no cardiovascular defects were reported with SGAs.[105]

Studies have shown differing results in regard to neonatal outcomes in infants exposed to SGAs in utero. Women with schizophrenia taking SGAs showed no significant risk of low birth weight (LBW), preterm birth, or infant considered small or large for gestational age (LGA) when compared to infants born to unaffected and unexposed mothers.[101] One prospectively designed study found a higher rate of LBW infants in mothers taking SGAs (10%) than in the reference group (2%),[102] while another recent prospective study reported higher rates of LGA infant births in women taking SGAs compared with those in the FGA and reference groups.[106]

Other potential interests in studying early and late exposure to antipsychotics include postnatal and gestational complications. Concern has been expressed regarding the use of clozapine in pregnancy.[107] The weight gain associated with olanzapine and clozapine and potential risk of gestational diabetes [108] should be considered in drug selection. Risk of neonatal EPS has been shown to be increased in those exposed in utero to FGAs, with effects in the infant lasting for 3 to 12 months after birth.[108] Other adverse neonatal outcomes reported in babies of mothers taking SGAs include respiratory complications and hypotonia.[108]

The risk of antipsychotic use must be weighed against the benefits of pharmacotherapy in pregnant women experiencing disorganized thoughts, delusions about change in body image or pregnancy, or who are unable to provide adequate prenatal care.[100]

Antipsychotics appear in breast milk with milk-to-plasma ratios of 0.5 to 1. However, 1 week after delivery, clozapine milk concentrations have been found to be as much as 279% of serum concentrations. Its use during breastfeeding is not recommended.[107] Overall, little is known about breast-feeding and the potential effects of antipsychotics on the neonate. Although not contraindicated, the lowest dosage should be used in the mother, and the infant should be carefully monitored.

DRUG INTERACTIONS

Most drug interactions occur because of pharmacodynamic or pharmacokinetic interactions. Common examples of pharmacodynamic interactions resulting in enhanced effect include the excess sedation that can occur when antipsychotics are used concomitantly with other medications that have sedative side effects. Additive antimuscarinic effects of antipsychotics used with other medications with antimuscarinic effects can result in urinary retention, constipation, blurred vision, or other anticholinergic side effects.[30,109] Both combined sedative and anticholinergic effects from multiple medications can result in impaired cognition, particularly in the elderly and other patients predisposed to such problems.[109] Patients are more likely to experience symptomatic orthostatic hypotension when an antipsychotic is used with other medications that cause orthostasis. Although metoclopramide is prescribed for treating esophageal reflux, it is a DA antagonist, and patients are more likely to experience akathisia and other EPS if it is used concomitantly with antipsychotics.[72] Although some SSRIs can interact with antipsychotics through enzyme inhibition, they can also interact through pharmacodynamic mechanisms. 5-HT_2 receptors are present on the presynaptic dopaminergic neuron, and their activation leads to decreased dopamine release from the presynaptic terminal. Increased availability of serotonin through SSRI effect can activate these receptors, decrease dopamine release, and add to the dopaminolytic effects of antipsychotics.[72] In the absence of enzyme inhibition, SSRIs can still precipitate akathisia or EPS when added to a patient stabilized on an antipsychotic. A potentially more dangerous interaction can occur when medications that slow myocardial conduction and thus prolong the QTc, are used in combination with antipsychotics that significantly prolong the QTc.[72] Medications that prolong the QTc should be monitored carefully in patients taking concomitant diuretics.[72] These effects can all increase the risk of clinically significant side effects.

Asenapine inhibits CYP2D6, and is the only SGA that has been shown to significantly affect the pharmacokinetics of other medications.[55] Table 76–6 lists the major pathways thought to be involved in the metabolism of SGAs. Risperidone is metabolized primarily by CYP2D6 to its active metabolite, 9-OH-risperidone (paliperidone), which is thought to have a similar pharmacodynamic profile.[72] CYP1A2 is the primary isoenzyme for metabolism of asenapine with CYP3A4 also being a significant pathway.[55]

Based on current information, inhibitors of CYP1A2 have the greatest potential for causing interactions with clozapine and olanzapine.[106] Examples include cimetidine, fluvoxamine, and fluoroquinolone antibiotics (e.g., ciprofloxacin) to varying degrees. To date, however, no serious inhibition interactions have been reported with olanzapine, which may be a result of olanzapine's wide therapeutic index. Carbamazepine has been reported to increase olanzapine elimination by as much as 50%.[110] Cigarette smoking is a potent inducer of CYP1A2, and one would expect lower mean olanzapine serum concentrations in smokers compared with nonsmokers.

Because of the risk of seizures with higher clozapine tissue concentrations, interactions which inhibit clozapine's metabolism are potentially significant. In particular, fluvoxamine increases clozapine serum concentrations by an average of two- to three-fold and up to five-fold.[110,111] Fluoxetine and erythromycin can increase clozapine serum concentrations in some patients but to a lesser degree.[110,111] Mean clozapine serum concentrations are reported to be 32% lower in smokers compared with nonsmokers.[110] Carbamazepine can induce clozapine metabolism and lead to lower serum concentrations.[110]

A study with the potent CYP3A4 inhibitor ketoconazole showed minimal effects on ziprasidone single-dose pharmacokinetics, with only a 33% mean increase in the ziprasidone area under the time-versus-concentration curve.[72] These results are consistent with data suggesting that aldehyde oxidase is the major metabolic pathway for ziprasidone, with only 30% to 35% being metabolized by CYP3A4.[112]

Modest elevations of aripiprazole serum concentration occur in the presence of ketoconazole or quinidine, which inhibit CYP2D6 and 3A4, respectively. Carbamazepine has been reported to decrease aripiprazole serum concentrations.[53,111]

Since iloperidone is metabolized through CYP2D6 and 3A4, its clearance can be impaired by inhibitors of these pathways. Since iloperidone prolongs the QTc interval, these types

of interactions have the potential to be clinically significant. For example, it is recommended that the iloperidone dose be decreased by 50% when used with CYP2D6 inhibitors such as fluoxetine or paroxetine.[54]

Table 76–9 summarizes potential antipsychotic drug interactions.

PHARMACOECONOMIC CONSIDERATIONS

It is estimated that approximately 80% of individuals suffering their first schizophrenic break will have recurrent episodes and significant lifetime psychosocial dysfunction. In 2004, the direct cost of treating schizophrenia in the United States was estimated to be

TABLE 76-9 Common Potential Drug Interactions with Antipsychotic Medications

Pharmacodynamic Drug Interactions with Antipsychotics

Pharmacokinetic Drug Interactions with Antipsychotics

Mechanism of Interaction	*Examples of Interacting Drugs*			*Clinical Effect*
Induction of AP metabolism	*Aniepileptics* Carbamazepine Oxcarbazepine Phenobarbital Phenytoin *HIV protease inhibitors* Efavirenz Nivirapine	*Anti-infectives* Nafcillin Rifampin *Miscellaneous* Broccoli Brussel sprouts Chargrilled meat Glucocorticoids Insulin Modafinil Omeprazole	*Herbals* St. John's wort Smoking tobacco	↓ AP effect
Paliperidone The bioavailability of paliperidone is significantly increased when it is taken with food. Although this could increase paliperidone effect, including adverse effects, the clinical significance is undetermined.				
Quetiapine Inhibition of AP metabolism (CYP3A4)	*Antidepressants* Fluoxetine (norfluoxetine) Fluvoxamine Nefazodone *HIV protease inhibitors* Indinavir Nelfinavir Ritonavir Sequinavir	*Anti-infectives* Ciprofloxacin Clarithromycin Erythromycin Fluoconazole Ketoconazole Itraconazole	*Miscellaneous* Amiodarone Cimetidine Diltiazem Grapefruit juice Verapamil	↑ AP effect ↑ SE
Induction of AP metabolism	*Antiepileptics* Carbamazepine Oxcarbazepine Phenobarbital Phenytoin *HIV Protease Inhibitors* Efavirenz Nivirapine	*Anti-infectives* Rifampin *Miscellaneous* Glucocorticoids Modafinil	*Herbals* St. John's wort	↓ AP effect
Perphenazine and risperidone Note: Because risperidone's metabolite formed through CYP2D6 metabolism is active (paliperidone), the clinical significance of metabolic drug interactions with risperidone is undetermined.				
Inhibition of AP metabolism (CYP2D6)	*Antidepressants* Bupropion Clomipramine Doxepin Duloxetine Fluoxetine Paroxetine Sertraline *Antipsychotics* Chlorpromazine Haloperidol (reduced haloperidol) Perphenazine	*Miscellaneous* Amiodarone Cimetidine Chlorpheniramine Cocaine Diphenhydramine Cimetidine Haloperidol Hydroxyzine Methadone Quinidine		↑ AP effect ↑ SE
Induction of AP metabolism	Dexamethasone Rifampin			↓ AP effect
Ziprasidone The bioavailability of ziprasidone is increased twofold when it is taken with food. Consistent administration with food is recommended.				

AP, antipsychotic; DA, dopamine; EPS, extrapyramidal symptoms; 5-HT, serotonin; SE, side effect; SSRI, serotonin selective reuptake inhibitor; TCAs, tricyclic antidepressants.
(Data from references 54, 55, 109–112, 122.)

nearly $23 billion and the total costs were over $62.6 billion.[113] The public mental healthcare sector provides the majority of services for individuals with schizophrenia. Mental healthcare costs for schizophrenia represent disproportionate expenditures for crisis intervention and hospitalization as compared with comprehensive outpatient services oriented toward maintaining remission and improving psychosocial functioning. The suboptimal or inadequate funding provided for efficient ambulatory mental health services further increases the demand for hospitalization, which diverts revenues that might be available for outpatient services. This has created a vicious revolving door cycle and is a major challenge facing public mental healthcare.

The advent of more expensive SGAs, accompanied by limited resources, has forced mental healthcare organizations to examine the outcomes and related economics of treating patients with SGAs compared with traditional, largely generic FGAs. Although several retrospective database studies found total mental healthcare cost advantages for SGAs versus FGAs, in the prospective

effectiveness study, CATIE, total mental health costs were higher for SGAs than the FGA perphenazine, and these costs were driven by the higher acquisition costs of the SGAs.[114] Some studies have shown clozapine to result in lower overall mental healthcare costs, while others have shown no difference in costs compared with FGAs. Additionally, clozapine decreases suicidality more than comparator antipsychotics, and it is more effective in treatment-resistant schizophrenia.[115,116]

Despite mental health service utilization increasing 65% over the past decade, there has not been a corresponding decrease in the prevalence of mental disorders or in suicidality.[117] CATIE is the first prospective comparative effectiveness study to evaluate the clinical outcomes and costs associated with different treatments in schizophrenia. Until we have better information regarding the comparative effectiveness of different treatments and how to best implement these treatments, controversy regarding reimbursement for mental health services, including medication formulary decisions, will continue.

EVALUATION OF THERAPEUTIC OUTCOMES

Assessment of response has traditionally been done subjectively or empirically (a relative sense of how the clinician feels the patient is doing). A formal mental status examination (MSE) is used to structure the patient interview and focus on items related to appearance, mood, sensorium, intellectual functioning, and thought processes. However, the MSE is not specific for the measurement of drug response. ⑩ Clinicians should be trained to use simple, standardized psychiatric rating scales to assist in objectively rating patient drug responses.[32,118] The Brief Psychiatric Rating Scale (BPRS) and the Positive and Negative Symptom Scale (PANSS) were developed for use in clinical trials as research tools to quantify symptoms and improvement seen with antipsychotic treatment.[118] Objectively, the use of a numeric indicator (e.g., 20%, 30%, or 40% reduction in BPRS score) has been used to quantify overall symptom reduction and classify patients according to different degrees of response. However, these types of rating scales are too long and unwieldy to be routinely used within the time constraints of most clinical practices. Symptom scales used in clinical practice must be sufficiently brief to be used during an ordinary clinic visit (e.g., 15–30 minutes) while measuring both positive and negative symptoms, and being sufficiently representative of overall symptomatology. The four-item Positive Symptom Rating Scale and the Brief Negative Symptom Assessment are brief scales that meet such criteria (Table 76–10).[32,118] It is increasingly recognized that clinicians should be examining cognition as an outcome in treatment of schizophrenia. A brief cognition battery has been developed and validated, and it can be completed in 15 to 20 minutes.[119]

Similarly, the pharmacotherapeutic plan should include specific monitoring parameters for side effects. The plan should include how the potential side effect will be evaluated, and the frequency of assessment. Given the risk of weight gain, diabetes, and lipid abnormalities associated with many of the SGAs, a consensus task force led by the American Diabetes Association recommends the following baseline parameters before beginning antipsychotics: family history, weight, height, body mass index, waist circumference, blood pressure, fasting plasma glucose, and fasting lipid profile.[68] They also recommend follow-up monitoring of these parameters after beginning or changing SGAs. Weight should be monitored monthly for the first 3 months, and quarterly thereafter. The other parameters should be assessed at the end of 3 months and then annually. If normal, serum lipids can be monitored less often. Self-assessments can be a useful adjunct in treating the patient. Although the patient with schizophrenia may not always be accurate in evaluating symptom severity, the use of patient self-assessments increases patient engagement in care, enhances therapeutic alliance, and gives the clinician an opportunity to identify misconceptions the patient can have regarding symptoms associated with the illness, medication side effects, and the like.[118,120] Traditionally, clinicians have often accepted partial symptom response in schizophrenia as success, and have not been aggressive in attempting to achieve greater symptomatic remission. The advent of multiple different SGAs with varying, but overall favorable, side-effect profiles should encourage clinicians to be more assertive in attempting to achieve symptom remission. This is consistent with an increasing focus on remission as a goal of treatment and evolving recovery movements with an emphasis on consumerism in the care of the severely mentally ill.[21,22] A recent study showing how the Internet can be used to aid relapse prevention efforts gives us a glimpse of how consumerism may enhance and influence the care for schizophrenia in the future.[121]

TABLE 76-10 Brief Clinical Assessments for Monitoring Antipsychotic Response in Schizophrenia

4-Item Positive Symptom Rating Scale (PSRS)								
Use each item's anchor points to rate the patient.								
1. Suspiciousness	NA[a]	1	2	3	4	5	6	7
2. Unusual thought content	NA	1	2	3	4	5	6	7
3. Hallucinations	NA	1	2	3	4	5	6	7
4. Conceptual disorganization	NA	1	2	3	4	5	6	7
Each item is scored from 1 (not present) to 7 (extremely severe)							SCORE: _____	
Brief Negative Symptom Assessment (BNSA)								
Use each item's anchor points to rate the patient.								
1. Prolonged time to respond	1	2	3	4	5	6		
2. Emotion: Unchanging facial expression, blank, expressionless face	1	2	3	4	5	6		
3. Reduced social drive	1	2	3	4	5	6		
4. Poor grooming and hygiene	1	2	3	4	5	6		
Each item is scored from 1 (normal) to 6 (severe)					SCORE: _____			

[a] NA, not able to be assessed

To enhance consistency in ratings, the structured probes in the Administration Manual should be used each time the scales are used. The complete Administration Manual for the PSRS and the BNSA can be accessed from the appendices in the Texas Medication Algorithm Project Procedural Manual for Schizophrenia at the Texas Department of State Health Services Website *http://www.dshs.state.tx.us/mhprograms/TIMA.shtm*.

CONCLUSIONS

Schizophrenia is a complex disease with multiple ramifications for patients and their families. Treatment issues remain clouded by the fact that the etiology of the illness is unknown. It is clear that no single treatment modality is adequate to properly manage a patient with schizophrenia. Antipsychotics are the bedrock of treatment. Antipsychotics are not a panacea and have multiple adverse effects that limit their effectiveness. However, when used within the context of multidisciplinary treatment, antipsychotics improve symptoms so that patients can appropriately participate in psychosocial rehabilitation programs. Scientific advances continue to expand our understanding of CNS physiology and the abnormalities present in schizophrenia. Advances in our understanding of the pathophysiology of schizophrenia should, in turn, result in the development of treatments that are more specific and more effective. In practice, it is mandatory that clinicians appropriately use their expanding armamentarium. It is important that clinicians appreciate the pharmacodynamic basis for treatment interventions so that they can effectively design and implement rational pharmacotherapeutic regimens. Finally, it is critical that clinicians more objectively evaluate individual patient response to medication so that treatment can be optimized. With these strategies, the gap between practice and science can be narrowed and patients' lives benefited.

CHAPTER 77

Major Depressive Disorder

CHRISTIAN J. TETER, JUDITH C. KANDO, AND BARBARA G. WELLS

KEY CONCEPTS

1. Extensive treatment guidelines are available to assist in the treatment of major depressive disorder, including medication management. Clinicians treating individuals with major depressive disorder should be familiar with these guidelines.
2. When evaluating a patient for the presence of depression, it is essential to rule out medical causes of depression and drug-induced depression.
3. The goal of pharmacological treatment of depression is the resolution of current symptoms (i.e., remission) and the prevention of further episodes of depression (i.e., relapse or recurrence).
4. When counseling patients with depression who are receiving antidepressant medications, the patient should be informed that adverse effects might occur immediately, while resolution of symptoms may take 2 to 4 weeks or longer. Adherence to the treatment plan is essential to a successful outcome, and tools to help increase medication adherence should be discussed with each patient.
5. Antidepressants are generally considered equally efficacious in groups of patients with major depressive disorder. Therefore, other factors, such as age, side effects, and past history of response, are used to guide the selection of medication management.
6. When determining if a patient has been nonresponsive to a particular pharmacotherapeutic intervention, it must be determined whether the patient has received an adequate dose for an adequate duration and whether the patient has been medication adherent.
7. When evaluating response to an antidepressant, in addition to target signs and symptoms, the clinician must consider quality-of-life issues such as role, social, and occupational functioning. In addition, the tolerability of the agent should be assessed because the occurrence of side effects may lead to medication nonadherence, especially given the chronicity of the disease and need for long-term medication management.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

A diagnosis of major depressive disorder is given when an individual experiences one or more major depressive episodes without a history of manic, mixed, or hypomanic episodes. A major depressive episode is defined by the criteria listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*.[1] Depression is associated with significant functional disability, morbidity, and mortality.

Newer generations of antidepressants have provided pharmacological interventions that are effective and better tolerated than older agents like the tricyclic antidepressants (TCAs) and the monoamine oxidase inhibitors (MAOIs). In addition, substantial efforts have been undertaken to improve the ability of clinicians to recognize and appropriately treat the signs and symptoms of depression. This chapter focuses exclusively on the diagnosis and treatment of major depressive disorder.

1 In the absence of well-accepted evidence-based medicine for the medication management of major depressive disorder, the reader is referred to the *Practice Guideline for the Treatment of Patients with Major Depressive Disorder, Second Edition*, which is available at *www.psych.org*. This extensive document is a practical guide to the management of depression based upon the best available data as well as clinical consensus.[2]

EPIDEMIOLOGY

The true prevalence of depressive disorders in the United States is unknown. The National Comorbidity Survey Replication found that 16.2% of the population studied had a history of major depressive disorder in their lifetime, and more than 6.6% had an episode within the past 12 months.[3] Women are at increased risk of depression from early adolescence until their mid-50s, with a lifetime rate that is 1.7 to 2.7 times greater than for men.[4] Although depression can occur at any age, adults 18 to 29 years of age experience the highest rates of major depression during any given year.[3] The estimated lifetime prevalence of major depression in individuals aged 65 to 80 recently was reported to be 20.4% in women and 9.6% in men.[5] Depressive disorders are common during adolescence, with comorbid substance abuse, suicide attempts, and deaths occurring frequently in these young patients.[6,7] Depressive disorders and suicide tend to occur within families. For example, approximately 8% to 18% of patients with major depression have at least one first-degree relative (father, mother, brother, or sister) with a history of depression, compared with 5.6% of the first-degree relatives of those without depression.[8] Furthermore, first-degree relatives of patients with depression are 1.5 to 3 times more likely to develop depression than normal controls.[1,8,9] A recent meta-analysis found that the heritability of liability for major depression was 37%, whereas the remaining 63% of the variance in liability was due to individual-specific environment.[10] Therefore major depressive disorder is relatively common, occurs

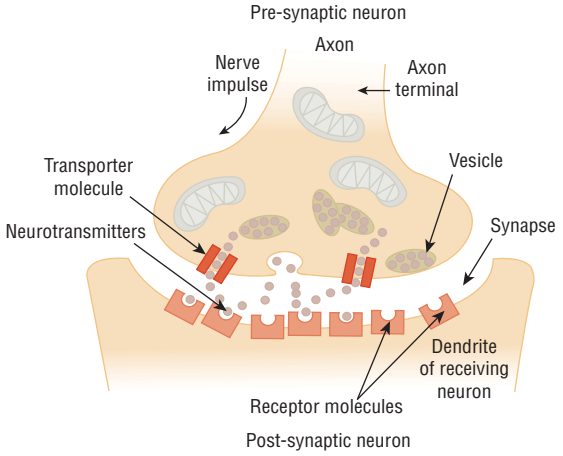

FIGURE 77-1. Monoamine neurotransmitter regulation at the neuronal level. Neurotransmitters (NTs) carry messages between cells. Each NT generally binds to a specific receptor, and this coupling initiates a cascade of events. NTs are reabsorbed back into nerve cells by reuptake pumps (i.e., transporter molecules) at which point they may be recycled for later use or broken down by enzymes. For their primary mechanism of action, most antidepressants are thought to inhibit the transporter molecules and allow more NT to remain in the synapse. *This figure was reproduced from the Mind Over Matter educational series, which is in the public domain and may be reproduced without permission. (Source: U.S. Department of Health and Human Services, National Institutes of Health, National Institute on Drug Abuse, Office of Science Policy and Communications, Science Policy Branch.)*

more frequently in women than men, and prevalence is influenced by both genetic and environmental factors.

ETIOLOGY

The etiology of depressive disorders is too complex to be totally explained by a single social, developmental, or biologic theory. Several factors appear to work together to cause or precipitate depressive disorders. The symptoms reported by patients with major depression consistently reflect changes in brain monoamine neurotransmitters, specifically norepinephrine (NE), serotonin (5-HT), and dopamine (DA).[11–13] Please see Figure 77–1 for a visual explanation as to how these monoamine neurotransmitters are regulated at the level of the neuron and within the synapse.

PATHOPHYSIOLOGY

Several years before the introduction of antidepressants, the cause of depression was linked to decreased brain levels of the neurotransmitters NE, 5-HT, and DA, although the actual cause remains unknown. This biogenic amine hypothesis evolved as a result of several observations made in the early 1950s. It was noted that the antihypertensive drug reserpine depleted neuronal storage granules of NE, 5-HT, and DA and produced clinically significant depression in 15% or more of patients.[14]

Although the reuptake blockade of monoamines (e.g., NE, DA, and 5-HT) occurs immediately upon administration of an antidepressant, the clinical antidepressant effects (i.e., measurable improvement) are generally delayed by weeks.[11,15] This delay may be the result of a cascade of events from receptor occupancy to gene transcription.[16] This delay in onset of action has caused researchers to focus on the adaptive changes induced by antidepressants.[12] Accordingly, theories that focus on adaptive (or chronic) changes in amine receptor systems have emerged over the past decade. In the mid-1970s, it was recognized that chronic, but not acute, administration of antidepressants to animals caused desensitization of NE-stimulated cyclic adenosine monophosphate synthesis. In fact, for most antidepressants, downregulation of β-adrenergic receptors accompanies this desensitization.[17] Studies of many antidepressants have demonstrated that either desensitization or downregulation of NE receptors corresponds to a clinically relevant time course for antidepressant effects.[11] Other studies have revealed desensitization of pre-synaptic 5-HT_{1A} autoreceptors following chronic administration of antidepressants.[18] Thus a theory based on changes in receptor sensitivity provides a cogent explanation of the delayed onset of therapeutic response of antidepressant drugs.[11] The dysregulation hypothesis incorporates the diversity of antidepressant activity with the adaptive changes occurring in receptor sensitization over several weeks. In this theory, emphasis is placed on a failure of homeostatic regulation of neurotransmitter systems rather than on absolute increases or decreases in their activities. According to this hypothesis, effective antidepressant agents restore efficient regulation to the dysregulated neurotransmitter system.[19]

It is apparent that no single neurotransmitter theory of depression is adequate. The 5-HT/NE link hypothesis maintains that both the serotonergic and noradrenergic systems are involved in an antidepressant response.[17] This hypothesis is also consistent with the rationale of the postsynaptic alteration theory of depression, which emphasizes the importance of β-adrenergic receptor downregulation for achieving an antidepressant effect.[17] Furthermore, both serotonergic and noradrenergic medications down-regulate β-adrenergic receptors, and there is a link between serotonin and norepinephrine.[17] This implies that medications that are effective in the treatment of depression act at both of these neurotransmitter systems.

Traditional explanations of the biologic basis of depressive disorders have focused largely on NE and 5-HT; however, most of the evidence that coalesced into the biogenic amine hypothesis of depression does not clearly distinguish between NE and DA. There is an abundance of evidence suggesting that dopamine transmission is decreased in depression and that agents that increase dopaminergic transmission have been found to be effective antidepressants.[20] Specifically, studies suggest that increased DA transmission in the mesolimbic pathway account for at least part of the mechanism of action of antidepressant medications.[20] The mechanisms by which antidepressant drugs alter DA transmission remain unclear, but may be mediated indirectly by primary actions at NE or 5-HT terminals. The complexity of the interaction between 5-HT, NE, and possibly DA is gaining greater appreciation, but a more in-depth understanding of the precise mechanism is needed.

More recent insight into the possible mechanisms underlying depressive disorders comes from studies on brain-derived neurotrophic factor (BDNF). BDNF is a growth factor protein that regulates the differentiation and survival of neurons. A growing body of evidence suggests this process might be disrupted in depressive disorders. More specifically, chronic stress and an associated increase in glucocorticoids such as cortisol may cause a disruption of BDNF expression in the hippocampus. This process may be prevented, or possibly even reversed, by antidepressant medications.[21] This is a relatively recent theory, which has not been firmly established. However, if proven valid, it demonstrates that antidepressants may help prevent deleterious effects of chronic stress and depressive symptoms.

BIOLOGIC MARKERS

Investigators continue to search for biologic or pharmacodynamic markers to assist in the diagnosis and treatment of depressed

patients. Although no biologic marker has been discovered, several biologic abnormalities are present in many depressed patients. Approximately 45% to 60% of patients with major depression have a neuroendocrine abnormality, including hypersecretion of cortisol or a lack of cortisol suppression after dexamethasone administration (i.e., a positive dexamethasone suppression test). In fact, it has been suggested that the inability of the brain to suppress the hypothalamic-pituitary-adrenal (HPA) axis and the associated stress response could lead to the pathophysiology and symptoms of depression.[22] According to this theory, there is a disruption somewhere in the normal negative feedback system that controls cortisol levels (please see Figure 85–3 in the Adrenal Gland Disorders chapter for a visual display of this negative feedback system). There are many potential negative consequences of excess circulating cortisol, including disruption in BDNF expression as discussed above in the Pathophysiology section.

Unfortunately, the high rate of false-positive and false-negative results associated with neuroendocrine abnormalities in depressed patients limits the usefulness of testing for these markers, and has led to their relative lack of use in clinical practice. However, they still provide a clue as to the potential pathophysiology of depressive disorders, which may lead us to more effective treatment options.

CLINICAL PRESENTATION

2 When a patient presents with depressive symptoms, it is necessary to investigate the possibility of a contributing medical or drug-induced etiology (Table 77–1). In fact, in the *DSM-IV-TR* there is a diagnostic category for both "Mood Disorder Due to a General Medical Condition" and "Substance-Induced Mood Disorder."[1] For example, up to 40% of patients with certain neurological disorders (e.g., stroke, Alzheimer's disease) develop depressive symptoms at some point during the course of their neurological illness.[1] Furthermore, individuals experiencing withdrawal from substances of abuse (e.g., cocaine) can present with depressive symptoms.[23] All depressed patients should have a complete physical examination, mental status examination, and basic laboratory workup, including a complete blood count with differential, thyroid function tests, and electrolyte determinations to identify any potential medical problems. Lastly, a complete medication review should be performed because several medications may contribute to depressive symptoms (Table 77–1).[24] Once a medical condition or concomitant medication has been ruled out as the cause of the depressive symptoms, the patient should be evaluated for a major depressive disorder.

According to the *DSM-IV-TR*, a single major depressive episode is characterized by five or more of the symptoms described in Table 77–2. At least one of the symptoms is depressed mood (often an irritable mood in children or adolescents) or loss of interest or pleasure in nearly all activities.[1] These symptoms must have been present nearly every day for at least 2 weeks and must represent a change from the patient's previous level of functioning. The clinician must consider presenting symptoms, their duration, and the patient's current level of social, occupational, or other important areas of functioning. Significant stressors or life events may trigger depression in some individuals but not others; and there may be an important precipitant at the beginning of the disorder.[1] A patient diagnosed with major depressive disorder may have one or more recurrent episodes of major depression during their lifetime.

DEPRESSION RATING SCALES

Instruments to assess the severity of depressive symptoms can be used for both clinical and research purposes. For example, the Montgomery-Åsberg Depression Rating Scale (MADRS) is a clinician-administered scale that is commonly used in drug trials given its sensitivity to change.[25] Other depression rating scales are self-administered. For example, the Beck Depression Inventory (BDI) takes only 5 to 10 minutes to complete by the respondent.[26] For a more detailed explanation for both of these instruments, as well as other rating scales and evaluation approaches, please refer to Chapter 71.

EMOTIONAL SYMPTOMS

A major depressive episode is characterized by a persistent, diminished ability to experience pleasure. A loss of interest and pleasure in usual activities, hobbies, or work is common. Patients appear sad

TABLE 77-1 Common Medical Conditions, Substance Use Disorders, and Medications Associated with Depressive Symptoms

General medical conditions
- Endocrine diseases
  - Hypothyroidism
  - Addison or Cushing disease
- Deficiency states
  - Pernicious anemia
  - Wernicke encephalopathy
  - Severe anemia
- Infections
  - AIDS
  - Encephalitis
  - Human immunodeficiency virus
  - Mononucleosis
  - Sexually transmitted diseases
  - Tuberculosis
- Collagen disorder
  - Systemic lupus erythematosus
- Metabolic disorders
  - Electrolyte imbalance
    - Hypokalemia
    - Hyponatremia
  - Hepatic encephalopathy
- Cardiovascular disease
  - Coronary artery disease
  - Congestive heart failure
  - Myocardial infarction
- Neurologic disorders
  - Alzheimer's disease
  - Epilepsy
  - Huntington disease
  - Multiple sclerosis
  - Pain
  - Parkinson's disease
  - Poststroke
- Malignant disease

Substance use disorders (including *intoxication* and *withdrawal*)
- Alcoholism
- Marijuana abuse and dependence
- Nicotine dependence
- Opiate abuse and dependence (e.g., heroin)
- Psychostimulant abuse and dependence (e.g., cocaine)

Drug therapy
- Antihypertensives
  - Clonidine
  - Diuretics
  - Guanethidine sulfate
  - Hydralazine hydrochloride
  - Methyldopa
  - Propranolol
  - Reserpine
- Hormonal therapy
  - Oral contraceptives
  - Steroids/adrenocorticotropic hormone
- Acne therapy
  - Isotretinoin
- Other
  - Interferon-β_{1a}

Data from references 1, 23, and 24.

TABLE 77-2 DSM-IV-TR Criteria for Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
   Note: Do not include symptoms that are clearly due to a general medical condition or mood-incongruent delusions or hallucinations.
   1. Depressed mood most of the day nearly every day
   2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day nearly every day
   3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day
   4. Insomnia or hypersomnia nearly every day
   5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
   6. Fatigue or loss of energy nearly every day
   7. Feelings of worthlessness or excessive or inappropriate guilt nearly every day
   8. Diminished ability to think or concentrate, or indecisiveness, nearly every day
   9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

D. The symptoms are not better accounted for by bereavement (i.e., after the loss of a loved one), the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright © 2000). American Psychiatric Association.

or depressed, and they are often pessimistic and believe that nothing will help them feel better. The presence of feelings of worthlessness or inappropriate guilt may identify patients at risk for suicide.[27] Anxiety symptoms are present in almost 90% of depressed outpatients. Patients often have guilt feelings that are unrealistic, and these may reach delusional proportions. Patients may feel that they deserve punishment and may view their present illness as a punishment. A patient suffering from major depression with psychotic features may hear voices (auditory hallucinations) saying that he or she is a bad person and that he or she should commit suicide. Depression with psychotic features may require hospitalization, especially if the patient becomes a danger to self or others.

PHYSICAL SYMPTOMS

Physical symptoms often motivate patients, especially the elderly, to seek medical attention. Chronic fatigue is a common complaint, with a decreased ability to perform normal daily tasks. Fatigue often appears worse in the morning and does not improve with rest. Complaints of pain, especially headache, often accompany fatigue.

Sleep disturbances generally present as frequent early morning awakening with difficulty returning to sleep. This may coexist with difficulty falling asleep and frequent nighttime awakening. Less frequently, depressed patients complain of increased sleep (hypersomnia), although they experience daytime exhaustion or fatigue.

Appetite disturbances, including complaints of decreased appetite, often result in substantial weight loss, especially in the elderly.[28] Some patients lose 2 pounds (0.9 kg) or more per week without dieting. Other patients, especially in the ambulatory setting, may overeat and gain weight, although they actually may not enjoy eating. They may crave specific foods. Some patients exhibit gastrointestinal complaints, others cardiovascular complaints, especially palpitations. Patients frequently present with a loss of sexual interest or libido.[29]

INTELLECTUAL OR COGNITIVE SYMPTOMS

Intellectual or cognitive symptoms include a decreased ability to concentrate, slowed thinking, and a poor memory for recent events. Patients may appear confused and indecisive. Depression should be considered when cognitive symptoms are present in the elderly.[28]

PSYCHOMOTOR DISTURBANCES

Patients may appear noticeably slowed or retarded in physical movements, thought processes, and speech (psychomotor retardation). Conversely, depression may be accompanied by psychomotor agitation, manifesting as purposeless, restless motion (e.g., pacing, wringing of hands, or outbursts of shouting).

SUICIDE RISK EVALUATION AND MANAGEMENT

The Centers for Disease Control and Prevention lists suicide as the eleventh leading cause of death among Americans and the second leading cause of death among 25- to 34-year-olds. In 2006, there were 91 suicides per day in the United States.[30] All patients diagnosed with major depression should be assessed for suicidal thoughts. Factors associated with an increased risk for suicide include psychiatric and substance use disorders, adolescence and younger age adults, physical illness, recent stressful life event, childhood trauma, hopelessness, and male gender.[31] Those with a higher level of risk have high degrees of suicidal intent and describe more specific plans, in particular, those that are violent and irreversible.[31] It is important to remember that the risk of suicide in those recovering from major depression may increase as they develop the energy and capacity to act on a plan made earlier in a course of illness. Additionally, despite factors to help identify those at greatest risk, it remains very difficult to predict suicidality in any given individual. Therefore, when suicidal intent is suspected, it is important to ask, "Are you thinking about harming or killing yourself?" If the risk is significant, the patient must be referred immediately to an appropriate healthcare professional. Additionally, certain depression rating scales, such as the MADRS discussed above, include questions that target suicidality, which may help identify those patients at risk.

In September 2004, the FDA required manufacturers of antidepressants to add a boxed warning stating that antidepressants increase the risk of suicidal thinking and behavior in short-term studies in children and adolescents with depressive disorders. These risks have become a new source of concern among those treating their patients with antidepressants. In order to help deal with the confusion these risks have caused, experts have recommended[32] the following:

- It is especially important to closely monitor patients for suicidal ideation and behavior at the beginning of treatment and among younger patients.
- Discuss the possibility that adverse events may occur, including behavioral agitation or anger, and encourage patients to seek help should this occur.
- Deal with the subject of suicide directly.

It is important to note that there is little evidence to suggest that withholding antidepressant treatment decreases the risk of eventual suicide and may actually increase the risk. Furthermore, it may be that longer-term medication is needed for any protective effects against suicidality.[32]

In May 2007, the FDA released additional requests to the makers of antidepressants that the black box warning regarding suicidality be expanded to include warnings about the increased risk of suicidality (thinking and behavior) in young adults 18 to 24 years of age, during the initial stages of treatment.

TREATMENT

DESIRED OUTCOME

The goals of treatment are to reduce the symptoms of acute depression, facilitate the patient's return to a level of functioning like that before the onset of illness, and prevent further episodes of depression. Whether or not to hospitalize the patient is often the first decision that is made in consideration of the patient's risk of suicide, physical state of health, social support system, and presence of a psychotic depression.

GENERAL APPROACH TO TREATMENT

3 There are three phases of treatment for patients with major depressive disorder: (1) the *acute* phase lasting from 6 to 10 weeks in which the goal is remission (i.e., absence of symptoms); (2) the *continuation* phase lasting 4 to 9 months after remission is achieved, in which the goal is to eliminate residual symptoms or prevent relapse (i.e., return of symptoms within 6 months of remission); and (3) the *maintenance* phase lasting at least 12 to 36 months in which the goal is to prevent recurrence (i.e., a separate episode of depression).[2,33] The risk of recurrence increases as the number of past episodes increase. The duration of antidepressant therapy depends on the risk of recurrence. Some investigators recommend lifelong maintenance therapy for persons at greatest risk for recurrence (persons younger 40 years of age with two or more prior episodes and persons of any age with three or more prior episodes).[2]

4 Educating the patient and their support system (e.g., family and friends) regarding the delay in antidepressant effects and the importance of adherence should occur before and during the entire course of treatment. The treatment of major depressive disorder generally includes nonpharmacologic and pharmacologic strategies, which are discussed in further detail below.

NONPHARMACOLOGIC THERAPY

In addition to pharmacologic interventions, psychotherapy should be employed whenever the patient is able and willing to participate. Psychotherapy alone is not recommended for the acute treatment of patients with severe and/or psychotic major depressive disorder. However, if the depressive episode is mild to moderate in severity, psychotherapy may be the first-line therapy.[34] The effects of psychotherapy and antidepressant medications are considered to be additive. Combined treatment may be advantageous for patients with partial responses to either treatment alone and for those with a chronic course of illness. However, for uncomplicated, nonchronic major depressive disorder, combined treatment may provide no unique advantage.[34] Although not extensively evaluated, cognitive therapy, behavioral therapy, and interpersonal psychotherapy appear equally effective.[34] Maintenance psychotherapy as the sole treatment to prevent recurrence generally is not recommended. Often, medication alone may prevent a depressive recurrence during the maintenance phase.[34]

Electroconvulsive therapy (ECT) is a safe and effective treatment for certain severe mental illnesses, including major depressive disorder as well as other selected psychiatric illnesses. Patients with depression are candidates for ECT when a rapid response is needed, risks of other treatments outweigh potential benefits, there is a history of poor response to antidepressants and a history of good response to ECT, and the patient expresses a preference for ECT.[35] A course of ECT generally consists of either unilateral or bilateral ECT administered 2 to 3 times weekly for a total of 6 to 12 treatments. A rapid therapeutic response (10–14 days) has been reported. Although there are no absolute contraindications to the use of ECT, several conditions are associated with increased risk. These include increased intracranial pressure, cerebral lesions, recent myocardial infarction, recent intracerebral hemorrhage, bleeding, or otherwise unstable vascular condition. The use of an anesthetic as well as a nondepolarizing neuromuscular blocking agent decreases the morbidity associated with ECT.[35] Adverse effects of ECT include cognitive dysfunction, cardiovascular dysfunction, prolonged apnea, treatment-emergent mania, headache, nausea, and muscle aches. Cognitive changes associated with ECT include confusion immediately after the seizure and retrograde and anterograde memory disturbance. Most cognitive disturbances are transient, but some patients may report permanent loss of memory for events occurring over the months before, after, or during treatment.[35] Relapse rates during the year immediately following ECT are high unless maintenance antidepressant medication is prescribed. Guidelines developed by the American Psychiatric Association include indications and contraindications for the appropriate use of ECT, procedures for obtaining informed consent, and issues in administering ECT.[35]

Another nonpharmacologic treatment for depression is bright light therapy. Bright light therapy consists of the patient gazing into a 10,000-lux intensity light box, which is slanted downward toward the patients face for approximately 30 minutes/day. It has shown effectiveness for treating both the winter "blues," also known as seasonal affective disorder (SAD), and for adjunctive use in major depressive disorder with seasonal exacerbations.[2] Light therapy is well tolerated, with minor visual complaints being the most frequently reported event.[36] Consequently, anyone undergoing light therapy should receive baseline and periodic eye examinations. The combination of bright light therapy and an antidepressant may provide additional benefit beyond either approach alone.[2]

PHARMACOLOGIC THERAPY

Antidepressants can be classified in several ways, including by chemical structure and the presumed mechanism of antidepressant activity. Although the link between the presumed mechanism of drug action and antidepressant response is tenuous, this classification has the advantage of being based on established pharmacology and clearly explains some of the common, but expected, adverse effects. The knowledgeable clinician can use these facts to tailor treatment to individual patient needs and thereby optimize treatment outcome. Currently available antidepressants and initial dosages are shown in Table 77–3.

5 Studies have found that antidepressants are of equivalent efficacy in groups of patients when administered in comparable doses. Because one cannot predict which antidepressant will be the most effective in an individual patient, the initial choice is made empirically. Factors that often influence the choice of an antidepressant include the patient's history of response, pharmacogenetics (history of familial antidepressant response), patient's concurrent medical history, presenting symptoms (e.g., fatigue as compared with psychomotor agitation), potential for drug–drug interactions, adverse events profile, patient preference, and drug cost.

Although the pathophysiology of major depression remains elusive, the clinician can now select from multiple approved drug therapies with different mechanisms of action.[2] Failure to respond to one antidepressant class or one antidepressant drug within a class

TABLE 77-3 Adult Dosages for Currently Available Antidepressant Medications[a]

Generic Name	Trade Name	Suggested Therapeutic Plasma Concentration ng/mL (nmol/L)	Initial Dose (mg/day)	Usual Dosage Range (mg/day)
Serotonin selective reuptake inhibitors				
Citalopram	Celexa		20	20–60
Escitalopram	Lexapro		10	10–20
Fluoxetine	Prozac		20	20–60
Fluvoxamine	Luvox		50	50–300
Paroxetine	Paxil		20	20–60
Sertraline	Zoloft		50	50–200
Serotonin/norepinephrine reuptake inhibitors				
Venlafaxine	Effexor		37.5–75	75–225
Desvenlafaxine	Pristiq		50	50
Duloxetine	Cymbalta		30	30–90
Aminoketone				
Bupropion	Wellbutrin		150	150–300
Triazolopyridines				
Nefazodone	Serzone		100	200–600
Trazodone	Desyrel		50	150–300
Tetracyclic				
Mirtazapine	Remeron		15	15–45
Tricyclics				
Tertiary amines				
Amitriptyline	Elavil	120–250 (433–903)[b]	25	100–300
Clomipramine	Anafranil		25	100–250
Doxepin	Sinequan		25	100–300
Imipramine	Tofranil	200–350 (713–1248)[c]	25	100–300
Secondary amines				
Desipramine	Norpramin	100–300 (375–1126)[c]	25	100–300
Nortriptyline	Pamelor	50–150 (190–570)	25	50–200
Monoamine oxidase inhibitors				
Phenelzine	Nardil		15	30–90
Selegeline (transdermal)	Emsam		6[d]	6–12[d]
Tranylcypromine	Parnate		10	20–60

[a]Doses listed are total daily doses; elderly patients are usually treated with approximately one-half of the dose listed.
[b]Parent drug plus metabolite.
[c]It has been suggested that combined imipramine + desipramine concentrations should fall between 150–240 ng/mL (535–900 nmol/L).
[d]Transdermal delivery system designed to deliver stated dose continuously over a 24-hour period.
Data from references 2, 15, 33, 42, and 67.

does not predict a failed response to another drug class or another drug within the class. Approximately 65% to 70% of patients with varying types of depression improve with drug therapy, compared with 30% to 40% who are well documented to improve with placebo.

MIXED SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

Although TCAs are effective in treating all depressive subtypes, their use has diminished greatly due to the availability of equally effective therapies that are much safer in overdose and better tolerated. All TCAs potentiate the activity of NE and 5-HT by blocking their reuptake. However, the potency and selectivity of TCAs for the inhibition of reuptake of NE and 5-HT vary greatly among these agents (Table 77–4). Because TCAs affect other receptor systems including the cholinergic, neurologic, and cardiovascular systems, adverse events are reported frequently during TCA therapy.[15]

Venlafaxine inhibits 5-HT reuptake at low doses, and NE reuptake at higher doses; thus, it is referred to as a *serotonin-norepinephrine reuptake inhibitor* (SNRI). The primary active metabolite of venlafaxine (i.e., desvenlafaxine) is also an SNRI and has been approved to treat depressive disorders. Duloxetine is an SNRI with both 5-HT and NE reuptake inhibition across all doses. Some studies suggest that the SNRIs may be associated with higher rates of response and remission than other antidepressants; however, most of these studies involved venlafaxine, and not all studies support this conclusion.[37]

SEROTONIN SELECTIVE REUPTAKE INHIBITORS

The efficacy of serotonin selective reuptake inhibitors (SSRIs) is superior to placebo and comparable to other classes of antidepressants in treating patients with major depression.[2,33] SSRIs are generally chosen as *first-line antidepressants* due to their safety in overdose and improved tolerability. Furthermore, the decision as to which SSRI to use *within* the class is typically based on the nuances of each medication, such as differences in drug interaction profile and other pharmacokinetic parameters (e.g., half-life), or due to cost considerations. These concepts will be discussed in greater detail later in this chapter.

TRIAZOLOPYRIDINES

Trazodone and nefazodone have dual actions on serotonergic neurons, acting as both 5-HT_2 antagonists and 5-HT reuptake inhibitors. They may also enhance 5-HT_{1A}-mediated neurotransmission.[15] Trazodone blocks α_1-adrenergic and histaminergic receptors leading to increased side effects (e.g., dizziness and sedation) that limit its use as an antidepressant. Recently, a longer-acting extended

TABLE 77-4 Relative Potencies of Norepinephrine and Serotonin Reuptake Blockade and Side-Effect Profile of Antidepressant Drugs

[b]Venlafaxine: primarily 5-HT at lower doses, NE at higher doses and DA at very high doses.
[c]Duloxetine: balanced 5-HT and NE reuptake inhibition.
[d]Bupropion: also blocks dopamine reuptake.
Data from references 15, 33, 37, 39, and 42.

release preparation of trazodone was approved by the FDA. However, its place in the treatment of major depressive disorder is yet to be determined. Nefazodone's use as an antidepressant has declined as well after reports of hepatic toxicity began to emerge. The FDA-approved nefazodone labeling includes a black box warning describing rare cases of liver failure.[38] The triazolopyridines are effective agents in treating major depression; however, they both carry risks that limit their usefulness as antidepressants.

AMINOKETONE

Bupropion has no appreciable effect on the reuptake of 5-HT, while having reuptake properties at both the norepinephrine and dopamine reuptake pumps.[18,39] These pharmacological properties make bupropion unique among all currently available antidepressants.

TETRACYCLIC

Mirtazapine enhances central noradrenergic and serotonergic activity through the antagonism of central presynaptic α_2-adrenergic autoreceptors and heteroreceptors.[40] Furthermore, it antagonizes 5-HT_2 and 5-HT_3 receptors as well as histamine receptors. The antagonism of 5-HT_2 and 5-HT_3 receptors has been linked to lower anxiety and gastrointestinal side effects, respectively. Blockade of histamine receptors is associated with the sedative properties of mirtazapine.[18]

MONOAMINE OXIDASE INHIBITORS

MAOIs increase the concentrations of NE, 5-HT, and DA within the neuronal synapse through inhibition of the MAO enzyme. Studies have demonstrated that similarly to TCAs, chronic therapy causes changes in receptor sensitivity (i.e., downregulation of β-adrenergic, α-adrenergic, and serotonergic receptors).[41] The MAOIs phenelzine and tranylcypromine are nonselective inhibitors of MAO-A and MAO-B. Recently, a selegeline transdermal patch was approved by the FDA for treatment of major depressive disorder that allows inhibition of MAO-A and MAO-B in the brain, yet has reduced effects on MAO-A in the gut[42] (see tyramine interactions with MAOIs below).

ST. JOHN'S WORT

Increasingly, consumers are choosing alternative forms of therapy, such as herbal medications including St. John's wort. Evaluations have found mixed results regarding the efficacy of the active ingredient in St. John's wort, hypericum, when compared with placebo and other antidepressants.[43] St. John's wort is available as an over-the-counter medication. Although this may allow certain advantages such as reduced cost of therapy and self-treatment, it also has the potential to result in circumvention of the healthcare system. St. John's wort has been found to have significant drug interactions with commonly used medications.[43] Perhaps most disconcerting is the fact that herbal

medications are not regulated by the FDA, and manufacturers are not required to adhere to good manufacturing practices or provide proof of safety and/or efficacy. If St. John's wort is to be used, it should be administered under the guidance of a clinician trained in the treatment of depression, and a single-source product should be used continuously from a reputable and trusted manufacturer.

ADVERSE EFFECTS

Serotonin-Norepinephrine Reuptake Inhibitors

The adverse effects of antidepressant medications are summarized in Table 77–4. The TCAs affect several neurotransmitters and produce a wide range of pharmacologic actions, including several unwanted, but expected, adverse effects. The most commonly occurring side effects are dose-related and are associated with blockade of cholinergic receptors (anticholinergic effects) and include dry mouth, constipation, blurred vision, urinary retention, dizziness, tachycardia, memory impairment, and at higher doses, delirium).[41] Although some tolerance does develop to these adverse effects, they have the potential to impact patient adherence, particularly in the elderly and those receiving long-term maintenance therapy. Orthostatic hypotension is a common, dose-related, and potentially problematic adverse effect that has been attributed to the affinity of the TCAs for adrenergic receptors.[44] TCAs also cause cardiac conduction delays and may even induce heart block in patients with a preexisting conduction disorder. TCA overdose can produce severe arrhythmias.[44] Furthermore, the FDA released a warning in December 2009 that the desipramine prescribing information will be changed to reflect an increased risk of death in patients receiving desipramine who have a *family history* of sudden cardiac death, cardiac dysrhythmias, and cardiac conduction disturbances. More on this reaction can be found at the FDA's MedWatch website. Therefore, caution should be exercised when prescribing these agents, especially in higher doses, to patients with clinically significant cardiac disease, and to patients with a family history of a cardiac event. Additional adverse effects that may lead to TCA nonadherence include weight gain and sexual dysfunction.[45] Abrupt withdrawal of TCAs is often associated with symptoms suggestive of cholinergic rebound (e.g., dizziness, nausea, diarrhea, insomnia, and restlessness), especially if the daily dose exceeds 300 mg.[46] Therefore, the dose should be tapered over at least several days.

The most commonly reported adverse effects with venlafaxine are similar to those of SSRIs and may be dose related; they include nausea, sexual dysfunction, and activation.[2] Venlafaxine may also cause a dose-related increase in diastolic blood pressure, and baseline blood pressure is not a useful predictor of the occurrence of this phenomenon. Blood pressure should be monitored regularly during venlafaxine therapy, and dosage reduction or discontinuation may be necessary if sustained hypertension occurs.[47] Duloxetine was relatively well tolerated in short-term clinical trials; however, experience with long-term studies and in a larger population of patients will more clearly define the risks and benefits of this newly approved antidepressant. The most commonly reported adverse events were nausea, dry mouth, constipation, decreased appetite, insomnia, and increased sweating.[37,48]

Serotonin Selective Reuptake Inhibitors

The SSRIs include fluoxetine, citalopram, sertraline, paroxetine, escitalopram, and fluvoxamine. These drugs have a low affinity for histaminic, α_1-adrenergic, and muscarinic receptors, and therefore they produce fewer anticholinergic and cardiovascular adverse effects than the TCAs, and are not usually associated with significant weight gain.[49,50,51] The most common adverse effects, which generally are mild and short lived, are gastrointestinal symptoms (i.e., nausea, vomiting, and diarrhea), sexual dysfunction in both males and females, headache, and insomnia.[50] A discontinuation or withdrawal syndrome may occur if SSRIs are abruptly discontinued. However, the longer the half-life of the drug and its active metabolite, the less likely a withdrawal syndrome will occur.[51,52] Although SSRIs are known to improve the anxiety symptoms associated with depression, a few patients experience an increase in anxiety symptoms or agitation early in treatment.

Triazolopyridines

Trazodone and nefazodone have minimal anticholinergic effects and 5-HT agonist side effects, but they can cause orthostatic hypotension. Sedation, cognitive slowing, and dizziness are the most frequent dose-limiting side effects associated with trazodone.[41] Common adverse effects associated with nefazodone include light-headedness, dizziness, orthostatic hypotension, somnolence, dry mouth, nausea, and asthenia (weakness). Due to the previously discussed potential for hepatic injury associated with nefazodone use treatment should not be initiated in individuals with active liver disease or with elevated baseline serum transaminases.[38] A rare but potentially serious adverse effect of trazodone is priapism, which is reported to occur in approximately 1 in 6,000 male patients. Some cases have required surgical intervention (1 in 23,000), and permanent impotence may result.[53] There have been no reports of priapism associated with nefazodone use in men, but there is a published case report of nefazodone-induced clitoral priapism.[54]

Aminoketone

Adverse effects associated with bupropion include nausea, vomiting, tremor, insomnia, dry mouth, and skin reactions. The occurrence of seizures in patients taking bupropion appears to be strongly dose related, and may be increased by predisposing factors such as history of head trauma and CNS tumor. Additionally, bupropion use is contraindicated in patients with eating disorders such as bulimia and anorexia, as these patients are prone to electrolyte abnormalities and are therefore at higher risk for seizure activity. At daily doses of 450 mg (the FDA-approved maximum dose) or less, the incidence of seizures is 0.4%.[55] Due to its pharmacological profile (i.e., pro-adrenergic) bupropion may cause activation or agitation in some patients.[18]

Tetracyclic

The most common adverse effects of mirtazapine are somnolence, weight gain, dry mouth, and constipation. Interestingly, side effects such as weight gain may be less with larger mirtazapine doses due to different mechanisms of action at different doses,[51] such as increased noradrenergic transmission as the dose is increased.

Monoamine Oxidase Inhibitors

The most common adverse effect of MAOIs is postural hypotension; this is more likely to occur with phenelzine than with tranylcypromine and may be minimized through divided dosage scheduling. Other common adverse effects include weight gain and sexual side effects (e.g., decreased libido, anorgasmia).[2] Phenelzine, the most frequently prescribed MAOI, has mild to moderate sedating effects, while tranylcypromine may exert a stimulating effect, and therefore insomnia can occur. In addition, fever, myoclonic jerking, and brisk deep tendon reflexes may occur.[56]

Hypertensive crisis, a potentially serious and life-threatening but rare adverse reaction, may occur when MAOIs are taken concurrently with certain foods, especially those high in tyramine

TABLE 77-5 Dietary Restrictions for Patients Taking Monoamine Oxidase Inhibitors[a]

Aged cheeses[b]
Sour cream[c]
Yogurt[c]
Cottage cheese[c]
American cheese[c]
Mild Swiss cheese[c]
Wine[d] (especially Chianti and sherry)
Beer
Herring (pickled, salted, dry)
Sardines
Snails
Anchovies
Canned, aged, or processed meats
Monosodium glutamate
Liver (chicken or beef, more than 2 days old)
Fermented foods
Canned figs
Raisins
Pods of broad beans (fava beans)
Yeast extract and other yeast products
Meat extract (marmite)
Soy sauce
Chocolate[e]
Coffee[e]
Ripe avocado
Sauerkraut
Licorice

[a]According to the FDA-approved Prescribing Information for the transdermal selegiline patch, patients receiving the 6 mg/24-hour dose are not required to modify their diet. However, patients receiving the 9 or 12 mg/24 hours are still required to follow the dietary restrictions similar to the other MAOIs.
[b]Clearly warrants absolute prohibition (e.g., English Stilton, blue, Camembert, cheddar).
[c]Up to 2 oz (59 mL) daily is acceptable.
[d]3 oz (89 mL) white wine or a single cocktail is acceptable.
[e]Up to 2 oz (59 mL) daily is acceptable; larger amounts of decaffeinated coffee are acceptable.

(Table 77–5), or medications (Table 77–6). Ten milligrams of tyramine can cause a marked pressor effect, and 25 mg can result in a serious hypertensive crisis.[57] These incidents may culminate in cerebrovascular accident and death. Symptoms of hypertensive crisis include occipital headache, stiff neck, nausea, vomiting, sweating, and sharply elevated blood pressure. Hypertensive crises can be treated with antihypertensive agents such as captopril.[58]

TABLE 77-6 Medication Restrictions for Patients Taking Monoamine Oxidase Inhibitors

Amphetamines	Local anesthetics containing sympathomimetic vasoconstrictors
Appetite suppressants	Meperidine
Asthma inhalants	Methyldopa
Buspirone	Methylphenidate
Carbamazepine	Other antidepressants[a]
Cocaine	Other MAOIs
Cyclobenzaprine	Reserpine
Decongestants (topical and systemic)	Rizatriptan
Dextromethorphan	Stimulants
Dopamine	Sumatriptan
Ephedrine	Sympathomimetics
Epinephrine	Tryptophan
Guanethidine	
Levodopa	

[a]Tricyclic antidepressants may be used with caution by experienced clinicians in treatment-resistant populations.
Recommended first-line drug interaction search engines: references 102 and 103.

Education of patients taking MAOIs regarding dietary and medication restrictions is extremely important. Printed and verbal patient instructions should be provided. It is important that patients be instructed to consult a healthcare professional before taking any over-the-counter medications, including non-FDA approved items sold as herbal/dietary supplements. Patients should be taught to recognize the symptoms of hypertensive crisis and to seek immediate treatment should those symptoms occur.

CLINICAL CONTROVERSY

In recent years, numerous reports from the Food and Drug Administration warn healthcare providers of adverse effects associated with the use of the antidepressants in various populations. Many of these warnings have been accompanied by product labeling changes, including black box warnings. However, some of the warnings have not been unequivocally supported in the scientific literature. Therefore, the reader is encouraged to examine and understand these reports, and consider them within the context of the scientific literature.

PHARMACOKINETICS

The pharmacokinetics of the antidepressants are summarized in Table 77–7. Bioavailability is low (30%–70% for most TCAs) as a result of the first-pass hepatic effect, which shows great interindividual variation.[59] The TCAs have a large volume of distribution and concentrate in brain and cardiac tissue in laboratory animals. They are bound extensively and strongly to plasma albumin, erythrocytes, α_1-acid glycoprotein, and lipoprotein.[59] The major metabolic pathways are demethylation, aromatic and aliphatic hydroxylation, and glucuronide conjugation. Enterohepatic cycling has been described.[59,60] Metabolism of TCAs is linear within the usual dosage range. The elimination half-lives of the TCAs can vary greatly among individual patients.[59]

Venlafaxine is metabolized to an active metabolite, O-desmethylvenlafaxine, which contributes to the overall pharmacological effect,[61] and has received FDA approval as another option for the treatment of depressive disorders. Venlafaxine has the lowest plasma protein binding of any antidepressant (27%–30%), which reduces the likelihood of drug interactions via this mechanism. As might be expected, different formulations of venlafaxine with different pharmacokinetic profiles have lead to different adverse effect profiles. For example, venlafaxine extended-release, with its sustained plasma concentrations, has been associated with higher rates of sexual dysfunction among men (37%) as compared with the immediate-release formulation (6%).[61]

The diversity of SSRIs is evident not only in their chemical structures, but also in their pharmacokinetic profiles.[62,63] These unique pharmacokinetic attributes of each SSRI can be used to guide treatment. For example, the long half-life of fluoxetine and its active metabolite norfluoxetine may be beneficial in instances of partial nonadherence (e.g., missed doses). Conversely, caution must be taken to monitor for drug–drug interactions prior to combining another medication with fluoxetine. SSRIs are extensively distributed to the tissues, and all, with the possible exception of citalopram and sertraline, may have a nonlinear pattern of drug accumulation with long-term administration.[49,62] Therefore, the relationship between the dose and observed effect (e.g., side effect) may change over time for the non-linear SSRIs, and this needs to be considered during treatment.

Bupropion is metabolized to multiple active metabolites (see Table 77–7). There are currently three formulations of bupropion (immediate release, sustained release, and extended release), which

TABLE 77-7 Pharmacokinetic Properties of Antidepressants

Generic Name	Elimination Half-Life (h)[a]	Time of Peak Plasma Concentration (h)	Plasma Protein Binding (%)	Percentage Bioavailable	Clinically Important Metabolites
Serotonin selective reuptake inhibitors					
Citalopram	33	2–4	80	≥80	None

[a]Biologic half-life in slowest phase of elimination.
[b]4–6 days with chronic dosing; norfluoxetine, 4–16 days.
[c]Increases 30%–40% when taken with food.
[d]No data available.
Data from references 37, 63, 70, and 71.

are considered bioequivalent.[64] The bupropion peak plasma concentrations are lower for the sustained-release formulation of bupropion, and it is believed this may contribute to a lower seizure risk with that formulation.[65]

Mirtazapine undergoes extensive biotransformation to several metabolites[66] and is primarily eliminated in the urine (renal elimination). However, these metabolites are present at such low plasma concentrations as to minimally contribute to the overall pharmacologic profile of mirtazapine.

Altered Pharmacokinetics

Factors that influence TCA plasma concentrations include disease states, genetics, age, cigarette smoking, and concurrent drug administration. Hepatic disease may result in increased TCA plasma concentrations.[67] Renal failure does not alter nortriptyline metabolism, but the 10-hydroxy metabolite may accumulate, and protein binding may be diminished, with resulting enhanced sensitivity to the drug.[59] Clinicians should be alert to the possibility of higher-than-expected plasma concentrations of some TCAs in the elderly.

In patients with cirrhosis, the half-lives of fluoxetine and norfluoxetine increased to 7.6 and 12 days, respectively.[62] Patients with hepatic impairment had a twofold increase in plasma concentrations of paroxetine.[68] Similarly, in patients with mild stable cirrhosis, the half-life of sertraline was 2.5 times greater than in patients without liver disease.[69] Patients with renal impairment had a 2- to 4-fold increase in paroxetine plasma concentrations compared with normal volunteers.[68] Plasma concentrations of SSRIs in the elderly are reported to be greater than in younger patients.[62]

The clearance of venlafaxine, mirtazapine, and their metabolites may be reduced among patients with hepatic or renal disease,[70] and doses should be adjusted accordingly. Elderly patients may require a dose reduction with mirtazapine.[70]

Plasma Concentration and Clinical Response

Studies in acutely depressed patients have demonstrated a correlation between antidepressant effect and plasma concentrations for some TCAs. However, the patient's clinical response, not plasma concentration, dictates dosage adjustments. Some patients with plasma concentrations outside the suggested therapeutic plasma concentration range respond, whereas others are nonresponsive regardless of their plasma concentration. See Table 77–3 for a listing of suggested therapeutic plasma concentration ranges. There are four TCAs (nortriptyline, desipramine, imipramine, and amitriptyline) with evidence to support an association between plasma concentrations and clinical response. However, the best established therapeutic range is for nortriptyline (50–150 ng/mL [190–570 nmol/L]),[67] which appears to demonstrate a curvilinear plasma concentration-response relationship.

For the newer antidepressants, a correlation has not been established between plasma concentration and clinical response or adverse effects.

Plasma Concentration Monitoring

Because of interindividual variations in plasma concentrations achieved by a given dose, interpretation of plasma concentrations

can be very difficult for the TCAs.[67] Although plasma level monitoring is not performed routinely, some indications include inadequate response, relapse, serious or persistent adverse effects, use of higher-than-standard doses, suspected toxicity, elderly patients, pregnant patients, cardiac disease, suspected nonadherence, suspected pharmacokinetic drug interactions, and when the manufacturer of the product changes. If plasma concentration monitoring is used to detect nonadherence, a cut-off as low as 30 ng/ml for the TCAs has been suggested to avoid confusion with low bioavailability or unusually rapid metabolism. Plasma concentrations should be obtained at steady state, usually after a minimum of 1 week at constant dosage. Sampling should be performed during the drug elimination phase, usually in the morning, 12 hours after the last dose. Samples collected in this manner are comparable for patients on once-, twice-, or thrice-daily regimens.[59]

DRUG INTERACTIONS

Serotonin-Norepinephrine Reuptake Inhibitors

Because the TCAs are metabolized in the liver through the cytochrome P450 system, they may interact with other drugs that modify hepatic enzyme activity or hepatic blood flow. TCAs are also extensively protein bound, which can cause drug interactions through displacement from protein-binding sites. Many commonly used medications can interact when given concurrently with TCAs. Due to their frequent co-administration, a common drug interaction occurs between the TCAs and certain SSRIs, such as paroxetine and fluoxetine. These drugs are known to inhibit cytochrome P450 (e.g., CYP 2D6) with the resultant increase in TCA plasma concentrations. Although MAOIs and TCAs may be coadministered safely in refractory patients with apparent increased efficacy compared with monotherapy, severe reactions (e.g., hypertensive crisis) and fatalities have occurred.[2,59] Therefore, this combination should be monitored extremely carefully. Lastly, the TCAs, SNRIs, and SSRIs can potentially be involved in a pharmacodynamic drug interaction known as the *serotonin syndrome (SS)*. This phenomenon will be described in further detail for SSRI drug interactions (i.e., the medications most commonly associated with this reaction) and within Table 77–8, which summarizes drug interactions for the newer-generation antidepressants.

Serotonin Selective Reuptake Inhibitors

Drug–drug interactions may occur when an SSRI is coadministered with another drug metabolized through the cytochrome P450 system. Two of the isoenzymes of the cytochrome P450 system, 2D6 and 3A4, are responsible for the metabolism of more than 80% of currently marketed drugs.[71] The ability of an SSRI, or any antidepressant, to inhibit or induce the activity of these enzymes will be a significant contributory factor in determining its capability to cause a pharmacokinetic drug interaction when administered concomitantly. Table 77–9 shows the cytochrome P450 enzyme inhibitory potential of the second- and third-generation antidepressant agents. In patients receiving a stable dose of any medication known to interact with SSRIs, if an SSRI is to be initiated, the starting dose should be low and titrated carefully to evaluate the potential importance of the interaction.

Certain pharmacodynamic drug interactions that may occur with SSRIs are concerning and require close monitoring. For example, the combination of an SSRI with another drug that augments serotonergic function (e.g., linezolid) can lead to SS, which is characterized by symptoms such as clonus, hyperthermia, and mental status changes.[72] However, these symptoms are not unanimously agreed upon (please see Clinical Controvery below for additional information). Therefore, a washout period of 2 to 5 weeks (depending on the half-life of the SSRI) may be necessary before the initiation of another serotonergic medication.

CLINICAL CONTROVERSY

Various criteria have been proposed for the diagnosis of SS. The typical triad of symptoms that has long been described includes mental status changes, autonomic instability, and neuromuscular abnormalities. However, SS has been identified in cases without all three of these symptoms being present. Therefore, alternative approaches to the well-accepted SS triad have been suggested. For example, it has been proposed[72] that the presence of any of the following symptom clusters is highly diagnostic of SS:

- Tremor + hyperreflexia
- Spontaneous clonus
- Muscle rigidity + temperature >38°C (100.4°F) + ocular clonus or inducible clonus
- Ocular clonus + agitation or diaphoresis
- Inducible clonus + agitation or diaphoresis

Other Agents

In contrast to the SSRIs that have potential for both pharmacokinetic and pharmacodynamic interactions, other newer-generation antidepressants such as venlafaxine, duloxetine, mirtazapine, and bupropion have drug interactions that are primarily pharmacodynamic. This may be partly explained by the relative lack of cytochrome P450 inhibition among these newer agents compared to SSRIs (see Table 77–9). As nefazodone use has been severely limited due to its potential to induce liver toxicity, and trazodone is primarily used as a non-FDA approved hypnotic at low doses, neither of these agents are likely to be involved in clinically significant drug interactions. However, it should be noted that nefazodone is a potent inhibitor of cytochrome P450 3A4.[71] Lastly, please refer to the MAOI adverse effects section above and Table 77–6 to read more about the hypertensive crisis that may result following the coadministration of MAOIs and other medications that increase the vasopressor response (e.g., amphetamines).

SPECIAL POPULATIONS

Elderly Patients

Depression in the elderly is a major public health problem. Many elderly depressed patients are inadequately treated, or depression is missed or mistaken for another disorder, such as dementia. In the elderly, depressed mood, the typical signature symptom of depression, may be less prominent than other depressive symptoms such as loss of appetite, cognitive impairment, sleeplessness, anergia, and loss of interest in and enjoyment of the normal pursuits of life.[73] Older adults may not recognize common symptoms associated with depression such as anhedonia (inability to experience pleasure), fatigue, and concentration difficulties. Somatic (physical) complaints are quite frequently the presenting symptoms in elderly depressed patients. Appropriate recognition and treatment of depression in the elderly is extremely important. In fact, individuals 65 years of age and older have a very high rate of suicidality.[74] Increased suicidal attempts present in the depressed elderly may

TABLE 77-8 Selected Drug Interactions of Newer-Generation Antidepressants

Antidepressant	Interacting Drug/Drug Class	Effect
Serotonin/norepinephrine reuptake inhibitors		
Venlafaxine and desvenlafaxine	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
Duloxetine	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Sibutramine	Serotonin syndrome
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
	Triptans	Serotonin syndrome
Serotonin selective reuptake inhibitors		
Citalopram and escitalopram	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Linezolid (*MAOI effects*)	Serotonin syndrome
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
Fluoxetine	Alprazolam	Increased plasma concentrations and half-life of alprazolam; increased psychomotor impairment
	Antipsychotics (e.g., haloperidol and risperidone)	Increased antipsychotic concentrations; increased extrapyramidal side effects
	β-Adrenergic blockers	Increased metoprolol serum concentrations; increased bradycardia; possible heart block
	Carbamazepine	Increased plasma concentrations of carbamazepine; symptoms of carbamazepine toxicity
	Linezolid (*MAOI effects*)	Serotonin syndrome
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Phenytoin	Increased plasma concentrations of phenytoin; symptoms of phenytoin toxicity
	TCAs	Markedly increased TCA plasma concentrations; symptoms of TCA toxicity
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
Fluvoxamine	Alosetron	Increased alosetron AUC (6-fold) and half-life (3-fold)
	Alprazolam	Increased AUC of alprazolam by 96%, increased alprazolam half-life by 71%; increased psychomotor impairment
	β-Adrenergic blockers	Fivefold increase in propranolol serum concentration; bradycardia and hypotension
	Carbamazepine	Increased plasma concentrations of carbamazepine; symptoms of carbamazepine toxicity
	Clozapine	Increased clozapine serum concentrations; increased risk for seizures and orthostatic hypotension
	Diltiazem	Bradycardia
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Methadone	Increased methadone plasma concentrations; symptoms of methadone toxicity
	Ramelteon	Increased AUC (190-fold) and C_{max} (70-fold)
	Sibutramine	Serotonin syndrome
	TCAs	Increased TCA plasma concentration; symptoms of TCA toxicity
	Theophylline and caffeine	Increased serum concentrations of theophylline or caffeine; symptoms of theophylline or caffeine toxicity
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
	Warfarin	Increased hypoprothrombinemic response to warfarin
Paroxetine	Antipsychotics (e.g., haloperidol, perphenazine and risperidone)	Increased antipsychotic concentrations; increased central nervous system and extrapyramidal side effects
	β-Adrenergic blockers	Increased metoprolol serum concentrations; increased bradycardia; possible heart block
	Linezolid (*MAOI effects*)	Serotonin syndrome
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	TCAs	Markedly increased TCA plasma concentrations; symptoms of TCA toxicity
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
Sertraline	Linezolid (*MAOI effects*)	Serotonin syndrome
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
Tetracyclic		
Mirtazapine	Carbamazepine	Mirtazapine concentration decrease (60%)
	MAOIs	Theoretically central serotonin syndrome could occur
Aminoketone		
Bupropion	MAOIs	Potential for hypertensive crisis
	Medications that lower seizure threshold	Increased incidence of seizures

AUC, area under the curve, C_{max}, maximum concentration; MAOI, monoamine oxidase inhibitor.

be due to access to firearms, diminished cognitive functioning, sleep disruptions, poor social interactions, and inattention among primary caregivers.[74]

Before initiating antidepressant treatment, a complete physical examination should be performed. In prescribing antidepressants, elderly patients may be either over- or undertreated. Overtreatment occurs when age-related pharmacokinetic and pharmacodynamic factors are overlooked. Undertreatment results from an overly conservative approach as a result of the patient's advanced age or concurrent medical problems. SSRIs are usually selected as first-choice antidepressants in the elderly, and this may enable the clinician to avoid some of the problematic adverse effects commonly associated with TCAs (e.g., sedative, anticholinergic, and cardiovascular-related side effects). Furthermore, there is evidence to suggest that the long-term use of antidepressants such as SSRIs in the elderly, administred with either psychotherapy or clinical management, may prevent a depressive relapse.[75] Bupropion and venlafaxine are often selected because of milder anticholinergic and less frequent cardiovascular side effects.[76] Mirtazapine has been shown to be an effective antidepressant in the elderly (at least 65 years of age) and better tolerated than SSRI paroxetine. Furthermore, secondary measures of anxiety and sleep were improved following mirtazapine administration.[77]

Pediatric Patients

Accumulating evidence indicates that childhood depression occurs quite commonly. Symptoms of depression in the young may vary from accepted diagnostic criteria and include several nonspecific symptoms such as boredom, anxiety, failing adjustment, and sleep disturbance.[78]

Data collected under controlled conditions that support the efficacy of antidepressants in children and adolescents are sparse, and no antidepressant, except fluoxetine, is FDA approved for the treatment of depression in patients younger than 18 years of age, although other antidepressants (e.g., sertraline) have been studied in this population.[79]

The use of antidepressants in children and adolsescents was complicated when, in March 2004, the FDA issued a black box warning in the product labeling for antidepressant medications warning clinicians and patients of the increased risk for suicidal ideation and behavior when antidepressants are used in this population. However, several retrospective longitudinal reviews of the use of antidepressants in children found no significant increase in the risk of suicide attempts or deaths.[80–82] Furthermore, adolescents suffering from depression who remain untreated may successfully commit suicide.[83,84] Further study is needed to resolve this important clinical dilemma.

Several cases of sudden death have been reported in children and adolescents taking antidepressants, such as desipramine. A baseline electrocardiogram (ECG) is recommended before initiating treatment with a TCA in children and adolescents, and many clinicians recommend an additional ECG when steady-state plasma concentrations are achieved.[85]

The treatment of depression in children remains challenging, as depression can be difficult to diagnose and treat once identified. Antidepressants are used to treat depressed children and adolescents because no other definitive effective therapies are currently available. Also, demonstration of efficacy in this population, as well as in adults, is confounded by a high placebo response rate. However, the TCAs and several of the SSRIs remain viable treatment options when prescribed and monitored appropriately.

Pregnant and Lactating Patients

Approximately 14% of pregnant women develop a serious depression during pregnancy.[86] The data presented in several recent publications should be considered when making treatment decisions for pregnant women suffering from major depression.[86–88] The first evaluation looked at the risk of discontinuing antidepressant therapy in pregnant women suffering from depression and found a significant risk of relapse. In this study, women who discontinued antidepressant therapy were 5 times more likely to have a relapse during their pregnancy than were women who continued treatment.[88] Another study utilized population health data to determine whether exposure to SSRIs and depression in pregnant women differs from exposure to maternal depression alone. The authors found that prenatal exposure to SSRIs was associated with an increased risk of low birth weight and respiratory distress, and that this relationship remained after accounting for maternal illness severity.[86] A study by Chambers and colleagues reported a 6-fold greater likelihood of the occurrence of persistent pulmonary hypertension of newborn infants exposed to an SSRI after the 20th week of gestation.[87] A recent editorial on the use of antidepressants in pregnancy lists four therapeutic principles to guide the clinician in treating women during pregnancy: (1) Pregnancy does not protect against the occurrence of depression, and the likelihood of relapse is very high in untreated women with recurrent illness. (2) Maternal depression adversely affects child development, and prenatal depression may adversely affect the offspring. (3) When attempting to balance benefit and risk, transient postnatal behavioral abnormalities in the offspring of treated mothers must not be assumed to portend long-term compromise. (4) SSRIs, the most commonly used and best-tolerated treatment for depression, carry a small but significant risk for a serious medical consequence.[89]

In September 2009, the American Psychiatric Association and the American College of Obstetricians and Gynecologists released a report discussing the treatment of depression during pregnancy. One of the prominent conclusions of this report was that *both* antidepressant treatment and untreated depression have been associated with potential problems during pregnancy. However, studies to date have not been able to adequately control for all the necessary variables involved in birth outcomes (e.g., maternal depressive disorder) and more work needs to be done.[90]

In summary, the risks and benefits of drug therapy during pregnancy must always be weighed, and concerns about the risks of untreated depression during pregnancy should be considered. These include the possibility of low-birth-weight secondary to poor maternal weight gain, suicidality, potential for hospitalization,

potential for marital discord, inability to engage in appropriate obstetric care, and difficulty caring for other children.[91] Several different approaches exist for dealing with pregnancy and antidepressant use. First, discontinuation of an antidepressant before conception is an option for women who are stable and appear likely to remain well while not taking antidepressant medication. Second, continuation of the antidepressant until conception may be reasonable. For those who have a history of depressive relapse after medication discontinuation, the antidepressant should be continued throughout pregnancy. Further evaluations of the newer antidepressant agents are needed to fully understand the risks associated with their use at various stages of the gestational period. Again, the risks of not treating depression in a pregnant woman should not be underestimated or minimized.

There is a great deal of uncertainty regarding long-term antidepressant exposure during breastfeeding due to the lack of data. However, sertraline and paroxetine both appear in relatively low concentrations in breast milk and in samples taken from infants.[92]

Relative Resistance and Treatment-Resistant Depression

The majority of "treatment-resistant" depressed patients are likely the result of inadequate therapy (relative resistance). This theory is supported by data from the National Institute of Mental Health (NIMH) Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, which is generally considered to be one of the premier antidepressant trials among patients with depressive disorders.[93] This study showed that one in three depressed patients who previously did not achieve remission using an antidepressant became symptom free with the help of an additional medication (e.g., bupropion SR) and one in four achieved remission after switching to a different antidepressant (e.g., venlafaxine XR).[93] Furthermore, patients can be switched to another medication within the same class. For example, patients in the STAR*D study not responding to an initial SSRI were shown to be as likely to respond to another SSRI as they were a medication from a different class.[94]

Although several different definitions for treatment-resistant depression have been proposed, the most widely accepted is depression which has not achieved remission even after two optimal antidepressant trails.[95] More than 40% of patients with major depressive disorder being treated with antidepressants meet these critera.[95] Three pharmacologic approaches that have been used with success for treatment resistant depression include the following:

1. The current antidepressant may be stopped and a trial with another agent initiated (i.e., switching). For example, the STAR*D trial compared switching to mirtazapine (up to 60 mg/day) versus nortriptyline (up to 200 mg/day) after two consecutive failed medication treatments.[96] In the mirtazapine group, 12.3% of patients met the remission criterion of a score of 7 or less on the HAM-D, while 19.8% of nortriptyline patients met this criterion at the end of 14 weeks.
2. The current antidepressant can be augmented by the addition of another agent such as lithium, or another antidepressant can be added (i.e., combination antidepressant treatment). For example, the STAR*D trial evaluated the addition of lithium or T_3 (i.e., triiodothyronine) to current antidepressant treatment. After approximately 10 weeks, T_3 augmentation resulted in higher remission rates (24.7%) compared with lithium (15.9%). However, the differences between these two augmentation strategies were modest and not statistically significant.[95]
3. The use of atypical antipsychotic agents to augment the antidepressant response. In fact, aripiprazole was the first atypical antipsychotic to receive FDA approval for adjunctive use in adults with major depressive disorder, and others will likely follow. Additionally, olanzapine *in combination* with fluoxetine (Symbyax) was approved for treatment resistant depression. Please refer to the FDA website for additional information on FDA approvals.

The American Psychiatric Association practice guideline for the treatment of patients with major depressive disorder offers guidance for managing patients who fail to respond. These guidelines advise that if patients fail to respond to medication after 6 to 8 weeks, a reappraisal of the treatment regimen should be considered.[2] Partial responders should consider changing the dose, augmenting the antidepressant, or adding psychotherapy or ECT. For those with no response, options include changing to a second antidepressant or the addition of psychotherapy or ECT. Comorbid medical or psychiatric conditions should be identified and treated because they may complicate treatment. Before changing a patient's treatment, the clinician is advised to evaluate the adequacy of the medication dosage and adherence with the prescribed regimen. A combination of two drugs should not be used when one drug will suffice.

6 Issues to be addressed in assessing the patient who has not responded to treatment include the following:

1. Is the diagnosis correct?
2. Does the patient have a psychotic depression?
3. Has the patient received an adequate dose and adequate duration of treatment?
4. Do adverse effects preclude adequate dosing?
5. Has the patient adhered to the prescribed regimen?
6. Was a stepwise approach to treatment used?
7. Was treatment outcome adequately measured?
8. Is there a coexisting or preexisting medical or psychiatric disorder?
9. Are there other factors that interfere with treatment?

CLINICAL APPLICATION

A suggested algorithm for the management of uncomplicated major depressive disorder is shown in Figure 77–2. Recommended initial doses and dosage ranges are shown in Table 77–3. In elderly patients, as a general rule, dosing is initiated at one-half the initial dose administered to younger adults, and the dose is increased at a slower rate.

The usual initial adult dose of most TCAs is 25 mg at bedtime, and the dose may be increased by 25 to 50 mg every third day. The usual starting dose of venlafaxine is 75 mg/day and taken with food. Some patients may better tolerate a starting dose of 37.5 mg/day for a few days before beginning 75 mg/day. Depending on tolerability, the dose is then titrated to 150 mg/day. If needed, the dose may be further increased to 225 mg/day. Severely depressed patients may require doses as high as 375 mg/day. Both an immediate-release and extended-release formulation of venlafaxine are now available. Desvenlafaxine can be started and maintained at the same 50 mg dose, which may be an advantage compared with other antidepressants that need to be titrated up over time. Duloxetine can be started at 30 mg and titrated upward to 60 to 90 mg/day, given as a divided or single daily dose.

The recommended initial dose for the SSRIs citalopram, fluoxetine, and paroxetine is 20 mg and 10 mg for escitalopram. The initial dose for fluvoxamine and sertraline is 50 mg/day. The doses are titrated upwards depending on symptom response and adverse effects.

Bupropion is usually initiated at 75 mg twice daily, and this dose may be increased to 100 mg 3 times daily after a few days. Most patients will respond at 300 mg/day; however, an increase to

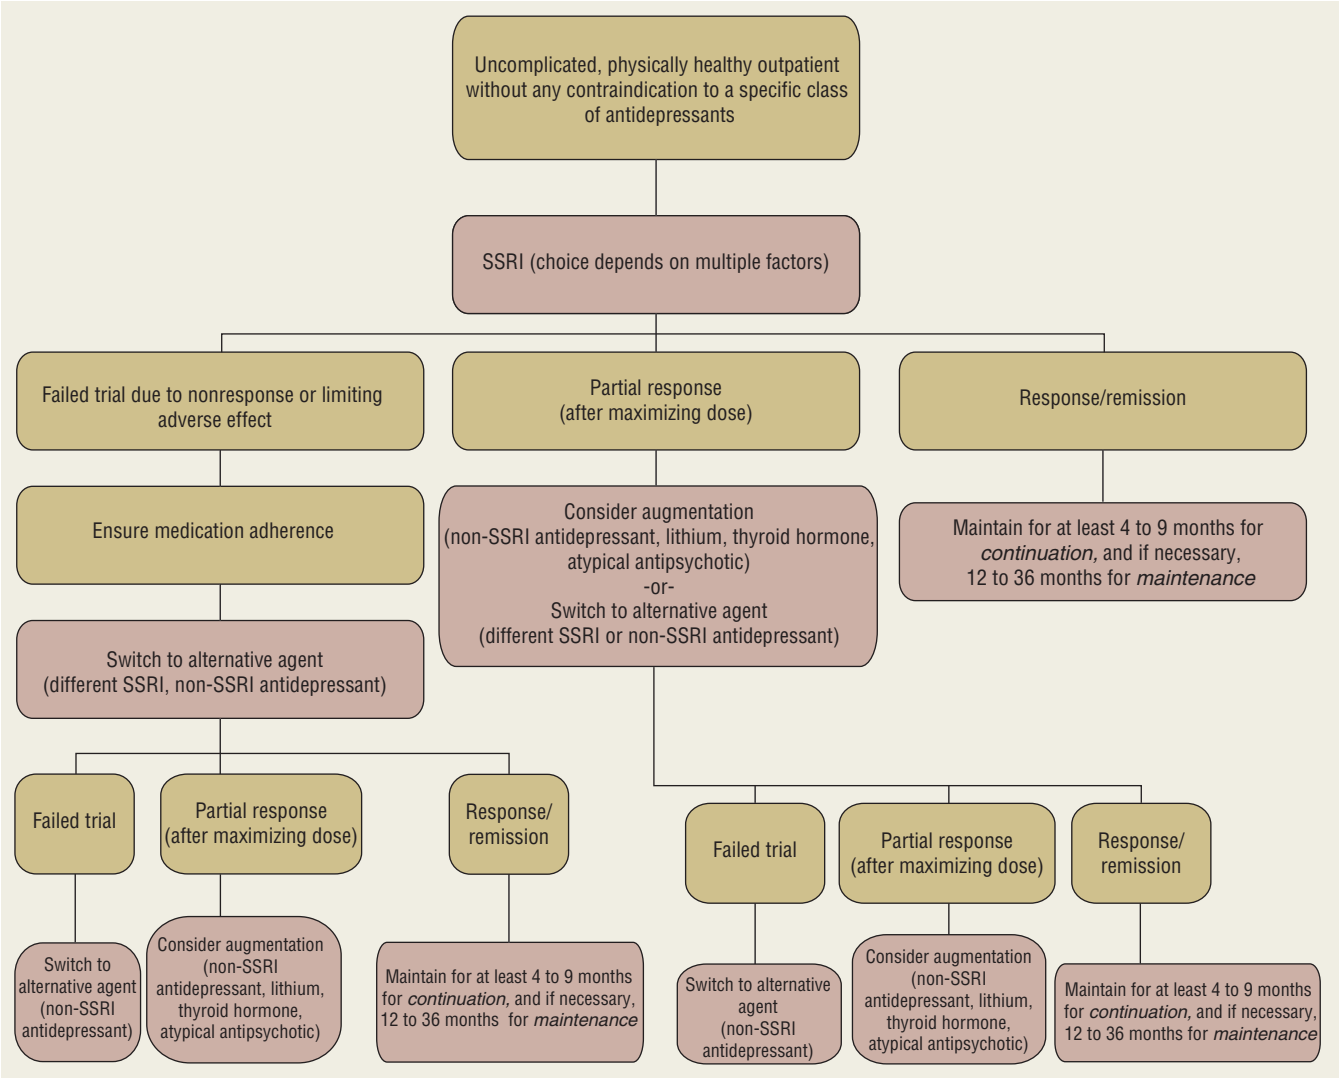

FIGURE 77-2. Algorithm for treatment of uncomplicated major depressive disorder. (SSRI, serotonin selective reuptake inhibitor.)

450 mg/day, given as 150 mg 3 times daily, may be considered in patients with no or partial response after several weeks of treatment at 300 mg/day. Additionally, both a 12-hour and 24-hour sustained-release formulation are available, allowing for less frequent dosing. The recommended starting dose of mirtazapine is 15 mg/day administered in a single dose at bedtime and the maximum recommended dose is 45 mg/day.

Caution is urged when switching from one antidepressant to another. It is important to remember that 3 to 4 weeks is usually required before a mood-elevating response is seen. A 6-week trial at a maximum dosage is considered an adequate trial.[2] It is crucial to counsel the patient about the expected lag time before the onset of clinical response. Patients uneducated in this regard often fail to adhere to their prescribed regimens.

PHARMACOECONOMIC CONSIDERATIONS

Cost of illness studies attempt to provide an estimation of the amount spent on a particular disease and to identify different components of the cost.[97] Ideally, direct, indirect, and intangible costs would be included. Direct costs include medical and nonmedical costs such as outpatient costs, inpatient costs, medication costs, transportation costs, and social services costs. Indirect costs include loss of productivity or reduced productivity. Intangible costs result from a decreased quality of life for the depressed individual and his/her family. Intangible costs are often not considered in pharmacoeconomic models because an accurate quantification in monetary terms is difficult.[97] Most published studies do not include all of the relevant aspects necessary for credible economic analyses.[98] In addition, there is wide variability among studies with regard to cost inclusion and evaluation of treatment withdrawals, relapses, toxicity, and adverse effects.[98] When SSRIs were introduced, many managed care organizations restricted these medications to those who had failed treatment with the TCAs or who had been unable to tolerate these agents, with the belief that the SSRIs represented a more expensive approach to the treatment of depression. One of the major claims for SSRIs is the greater tolerability and safety profile in overdose when compared with TCAs.[99] Studies including the costs associated with hospitalization following TCA overdoses, as opposed to SSRI overdoses, indicate that overdoses with TCAs are significantly more expensive.[99] All of the randomized clinical trials evaluating total expenditure of SSRIs versus TCAs indicate a cost-advantage associated with SSRIs. This advantage may be due to greater tolerability. Recently, several of the SSRIs have lost patent exclusivity, and generic versions of these medications are available at substantially lower prices than the brand name versions. Due to this generic availability, the restrictions placed on SSRIs have been removed from most, if not all, organizations.

Many of the new compounds, such as the SNRIs, are still restricted to second-line therapy or carry additional copay for the patient. This is likely to remain the case unless additional longer-term studies in more diverse populations are conducted that show an overall cost advantage for the newer agents. It would be extremely useful if cost-effective agents in various subpopulations and special populations (e.g., the elderly, those with comorbid substance abuse, those with comorbid anxiety disorders, and children) were identified. Also, the pharmacoeconomics of medication management in various healthcare environments such as public, private, psychiatry, or primary care, needs further exploration. Pharmacoeconomic studies conducted to date are difficult to generalize, as there are no widely accepted uniform criteria, and studies vary greatly in accounting for factors such as adherence, treatment withdrawals, relapses, toxicity, and adverse effects. There is also great variability in the type of costs included.[98]

EVALUATION OF THERAPEUTIC OUTCOMES

7 Several monitoring parameters, in addition to plasma concentrations, are useful in managing patients. Patients must be monitored for adverse effects, such as sedation, anticholinergic effects, and for remission of previously documented target symptoms. The presence of side effects does not necessarily indicate adequate dosage. In addition, changes in social and occupational functioning should be assessed. Patients receiving venlafaxine should have their blood pressure monitored at regular intervals. Patients older than 40 years of age should receive a pretreatment ECG before starting TCA therapy, and follow-up ECGs should be performed periodically. Patients should be monitored for the emergence of suicidal ideation after initiation of any antidepressant. Weight gain and sexual dysfunction, common events associated with most antidepressants, are associated with nonadherence and should be monitored and discussed with the patient.

In addition to the clinical interview, psychometric rating instruments (such as those highlighted earlier in this chapter and in Chapter 71) allow for rapid and reliable measurement of the nature and severity of depressive and associated symptoms. It is helpful to administer the rating scales prior to treatment, 6 to 8 weeks after initiation of therapy, and periodically thereafter. Interviewing a family member or friend (with the patient's permission) regarding symptoms and daily functioning also can assist in assessment of progress. Patients should be monitored at more frequent intervals early in treatment. Monitoring is then continued at regular intervals throughout the continuation and maintenance phases of treatment. Regular monitoring for reemergence of target symptoms should be continued for several months after antidepressant therapy is discontinued.

Finally, one useful set of criteria that can be used with a variety of psychometric scales was suggested by Mann.[33] Following these criteria, the following definitions are used: (1) *nonresponse* is less than 25% decrease in baseline symptoms, (2) *partial response* is a 26%–49% decrease in baseline symptoms, and (3) *partial remission or response* is greater than a 50% decrease in baseline symptoms. Consistent with other recommendations, *remission* is a return to baseline functioning with no symptoms present.[2]

COLLABORATIVE PRACTICE

Significant evidence exists to show that depression is common, chronic, and causes significant morbidity and mortality. Pharmacists, in conjunction with other healthcare providers, can play a crucial role in the screening, recognition, and treatment of this disorder. In fact, the U.S. Preventive Services Task Force recommends screening adults for depression in clinical practices that have systems in place to ensure accurate diagnosis, effective treatment, and follow-up.[100] In addition, pharmacists and other healthcare clinicians play a crucial role in ensuring adherence to medication regimens through assessment of a patient's willingness and ability to take a medication, including an assessment of financial viability, and through patient education regarding dosing, side effects and drug interactions, and guidance regarding follow-up appointments with prescribing clinicians.[101]

CONCLUSIONS

Major depressive disorder remains one of the most commonly occurring mental illnesses in adults, and it is often undiagnosed and untreated. Pharmacologic intervention is the cornerstone of treatment for major depressive disorder. Antidepressant medications have a broad spectrum of neurochemical effects and influence a variety of receptors peripherally and centrally. Safe and effective use of antidepressants requires a thorough understanding of the pharmacology of these drugs and of the principles of treatment monitoring. Clinicians must have a thorough understanding of antidepressant drug interactions and factors that may influence their pharmacokinetic parameters. Lastly, safe and effective use of antidepressants depends on patient adherence to the prescribed antidepressant regimen. Pharmacists are in an ideal position to accomplish all of these treatment goals and promote the appropriate medication management of major depressive disorder.

ABBREVIATIONS

BDNF: brain-derived neurotrophic factor

DA: dopamine

DSM-IV-TR: *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision*

ECG: electrocardiogram

ECT: electroconvulsive therapy

FDA: U.S. Food and Drug Administration

HPA: hypothalamic-pituitary-adrenal

CHAPTER 78

Bipolar Disorder

SHANNON J. DRAYTON

KEY CONCEPTS

1. Bipolar disorder is a cyclic mental illness with recurrent mood episodes that occur over a person's lifetime. The symptoms, course, severity, and response to treatment differ among individuals.
2. Bipolar disorder is likely caused by genetic factors, environmental triggers, and the dysregulation of neurotransmitters, neurohormones, and second messenger systems in the brain.
3. The goal of therapy for bipolar disorder should be to improve functioning of the patient by reducing mood episodes. This is accomplished by maximizing the adherence to therapy and limiting adverse effects.
4. Patients and family members should be educated about bipolar disorder and treatments. Long-term monitoring and adherence to treatment are major factors in obtaining stabilization of the disorder.
5. Lithium and valproate are the mainstays of treatment for both acute mania and prophylaxis for recurrent manic and depressive episodes. Anticonvulsants, such as lamotrigine, carbamazepine, and oxcarbazepine, and second-generation antipsychotics, such as aripiprazole, olanzapine, risperidone, quetiapine, and ziprasidone are alternative or adjunctive treatments for bipolar disorder. Anticonvulsants may be more effective than lithium in several mood subtypes (e.g., mixed states and rapid cycling). The use of lithium, valproate, or quetiapine for acute bipolar depression should be considered as first-line treatment options.
6. Baseline and follow-up laboratory tests are required for some medications to monitor for adverse effects.
7. Some patients can be stabilized on one mood stabilizer, but others may require combination therapies or adjunctive agents during an acute mood episode. If possible, adjunctive agents should be tapered and discontinued when the acute mood episode remits and the patient is stabilized. Adjunctive agents may include benzodiazepines, additional mood stabilizers or antipsychotics, and/or antidepressants.

1 Bipolar disorder (previously known as manic-depressive illness) is one of the most common of the severe chronic psychiatric disorders. The cyclic mood disorder is characterized by recurrent fluctuations in mood, energy, and behavior encompassing the extremes of human experiences.[1–3] Bipolar disorder differs from recurrent major depression (or unipolar depression) in that a manic, hypomanic, or mixed episode occurs during the course of the illness.[1] Bipolar disorder is a lifelong illness with a variable course and requires both nonpharmacologic and pharmacologic treatments for mood stabilization.[1,2]

EPIDEMIOLOGY

The lifetime prevalence of bipolar I disorder (one or more manic or mixed episodes) is 0.4% to 1.6%; that for bipolar II disorder (recurrent major depressive episodes with hypomanic episodes) is approximately 0.5%.[1,2] A national comorbidity survey reported that the lifetime prevalence rate of a manic episode is 1.6% ± 0.3% for men and 1.7% ± 0.3% for women in the United States (~4 million people).[4] Bipolar I disorder occurs equally in men and women, whereas bipolar II disorder is more common in women.[1,2]

ETIOLOGY

2 The exact etiology of bipolar disorder is unknown. Bipolar disorder is thought to be a complex genetic disease that is environmentally influenced and caused by a wide range of neurobiologic abnormalities. Stressful life events, alcohol or substance use, and changes in the sleep-wake cycle can elicit the expression of genetic or biologic vulnerabilities that cause dysregulation of neurotransmitters, neuroendocrine pathways, and second messenger systems.[3] Table 78–1 summarizes the etiologic theories of bipolar disorder.

PATHOPHYSIOLOGY

2 Many theories have been proposed regarding the pathophysiology of mood disorders.[3] Family, twin, and adoption studies report an increased lifetime prevalence risk of having mood disorders among first-degree relatives of patients with bipolar disorder.[2,5] Genetic linkage studies suggest multiple gene loci can be involved in the heredity of mood disorders.[6–10] Neuroimaging studies have found neurochemical, anatomic, and functional abnormalities in bipolar patients.[10,11] Environmental or psychosocial stressors, nutritional deficiencies, infections, immunologic reactions, sleep deprivation, and disruption of circadian rhythms can cause dysregulation in neurotransmitters, hormones, endocrine function, neuropeptides, cations, intracellular second messengers, and signal transduction pathways.[1,2,10–17]

TABLE 78-1 Etiologic Theories of Bipolar Disorder

Genetic factors

80%–90% of patients with bipolar disorder have a biologic relative with a mood disorder (e.g., bipolar disorder, major depression, cyclothymia, or dysthymia).
First-degree relatives of bipolar patients have a 15%–35% lifetime risk of developing any mood disorder and a 5%–10% lifetime risk for developing bipolar disorder.
The concordance rate of mood disorders is 60%–80% for monozygotic twins and 14%–20% for dizygotic twins.
Linkage studies suggest that certain loci on genes and the X chromosome may contribute to genetic susceptibility of bipolar disorder.

Nongenetic factors

Perinatal insult
Head trauma
Environmental factors
- Desynchronization of circadian or seasonal rhythms cause diurnal variations in mood and sleep patterns and can result in seasonal recurrences of mood episodes.
- Changes in the sleep-wake cycle or light-dark cycle can precipitate episodes of mania or depression.
- Bright light therapy can be used for the treatment of winter depression and can precipitate hypomania, mania, or mixed episodes.

Psychosocial or physical stressors
- Stressful life events often precede mood episodes and can increase recurrence rates and prolong time to recovery from mood episodes.

Nutritional factors
- Deficiency of essential amino acid precursors in the diet can cause a dysregulation of neurotransmitter activity (e.g., L-tryptophan deficiency causes a decrease in 5-HT and melatonin synthesis and activity).
- Deficiency in essential fatty acids (e.g., omega-3 fatty acids) can cause a dysregulation of neurotransmitter activity.

Neurotransmitter/neuroendocrine/hormonal theories
- Dysregulation between excitatory and inhibitory neurotransmitter systems; excitatory: NE, DA, glutamate, and aspartate; inhibitory: 5-HT and GABA.

Monoamine hypothesis
- An excess of catecholamines (primarily NE and DA) cause mania.
- Agents that decrease catecholamines are used for the treatment of mania (e.g., DA antagonists and α_2-adrenergic agonists).
- Deficit of neurotransmitters (primarily NE, DA, and/or 5-HT) cause depression.
- Agents that increase neurotransmitter activity are used for the treatment of depression (e.g., 5-HT and NE/DA reuptake inhibitors and MAOIs).

Dysregulation of amino acid neurotransmitters
- Deficiency of GABA or excessive glutamate activity causes dysregulation of neurotransmitters (e.g., increased DA and NE activity).
- Agents that increase GABA activity or decrease glutamate activity are used for the treatment of mania and for mood stabilization (e.g., benzodiazepines, lamotrigine, lithium, or valproic acid).

Cholinergic hypothesis
- Deficiency of acetylcholine causes an imbalance in cholinergic-adrenergic activity and can increase the risk of manic episodes.
- Agents that increase acetylcholine activity can decrease manic symptoms (e.g., use of cholinesterase inhibitors or augmentation of muscarinic cholinergic activity).
- Increased central acetylcholine levels can increase the risk of depressive episodes.
- Agents that decrease acetylcholine activity can alleviate depressive symptoms (i.e., anticholinergic agents).

Secondary messenger system dysregulation
- Abnormal G protein functioning dysregulates adenylate cyclase activity, phosphoinositide responses, sodium/potassium/calcium channel exchange, and activity of phospholipases. Abnormal cyclic adenosine monophosphate and phosphoinositide secondary messenger system activity.
- Abnormal protein kinase C activity and signaling pathways.

Hypothalamic-pituitary-thyroid axis dysregulation
- Hyperthyroidism can precipitate manic-like symptoms.
- Hypothyroidism can precipitate a depression and be a risk factor for rapid cycling; thyroid supplementation can be used for refractory rapid cycling and augmentation of antidepressants in unipolar depression.
- Positive antithyroid antibody titers reported in patients with bipolar disorder.
- Hormonal changes during the female life cycle can cause dysregulation of neurotransmitters (e.g., premenstrual, postpartum, and perimenopause).

Membrane and cation theories
- Abnormal neuronal calcium and sodium activity and homeostasis cause neurotransmitter dysregulation.
- Hypocalcemia has been associated with causing anxiety, mood irritability, mania, psychosis, and delirium.
- Hypercalcemia has been associated with causing depression, stupor, and coma.
- Extracellular and intracellular calcium concentrations may affect the synthesis and release of NE, DA, and 5-HT, as well as the excitability of neuronal firing.

Sensitization and kindling theories
- Recurrences of mood episodes cause behavioral sensitivity and electrophysiologic kindling (similar to the amygdala-kindling models for seizures in animals) and can result in rapid or continuous mood cycling.

DA, dopamine; GABA, γ-aminobutyric acid; 5-HT, serotonin; MAOI, monoamine oxidase inhibitor; NE, norepinephrine.
Data from Goldberg and Harrow,[3] Kelso,[6] Lenox et al.,[7] Baron,[8] Bezchlibnyk and Young,[9] Goodnick,[10] Soares,[11] Manji et al.,[13] Gould and Manji,[14] Sobczak et al.,[15] Freeman et al.,[16] Ketter and Wang,[17] White,[18] Rasgon et al.,[19] and Mahmood and Silverstone.[20]

NEUROCHEMICAL THEORIES

The kindling and behavioral sensitization model postulates that psychosocial stressors can result in manic or depressive episodes because various brain networks are sensitized for exaggerated and spontaneous reactions secondary to neurotransmitter imbalances or dysregulation and voltage-gated ion channel abnormalities.[3,18] Dysregulation between neurotransmitters, neuropeptides, hormones, and secondary messenger systems can produce a cyclic rhythm disturbance in the central nervous system.[3,11,12,18] Abnormal calcium, potassium, and sodium homeostasis can alter neurotransmitter release and the secondary messenger system.[12,18] Hormonal changes during the menstrual cycle, postpartum period, and perimenopausal phase can contribute to mood dysregulation.[16,19]

The "permissive serotonin hypothesis" proposes that serotonin (5-hydroxytryptamine [5-HT]) plays a critical role in modulating brain activity (e.g., stabilization of the catecholamine system and inhibition of dopamine [DA] release), and is low in both mania and depression.[10] The hypothesis further states that the type of

affective state that is expressed is determined secondarily by the level of norepinephrine (NE) (e.g., increased amounts of NE lead to mania, decreased amounts lead to depression). L-tryptophan or 5-HT deficiency and changes in the light-dark cycle may result in reduced melatonin secretion from the pineal gland that disrupts the sleep-wake cycle, alters circadian rhythms, and causes seasonal affective changes.[10,20]

The catecholamine hypothesis of mood disorders suggests that increased DA and NE activity contribute to hyperactivity and psychosis associated with the severe stages of mania, and reduced DA and NE activity causes depression.[3,10] A γ-aminobutyric acid (GABA) deficiency theory has been proposed for mania as it inhibits NE and DA activity.[3,10,12] Glutamate and aspartate, excitatory amino acid neurotransmitters, may be overactive and involved in causing manic episodes.[12] Cholinergic underactivity has been proposed to cause mania and overactivity of acetylcholine to cause depression.[10,12] Acetylcholine is an antagonist of the catecholamine system and contributes to the interaction between phosphatidylinositol and phosphatidylcholine secondary messenger systems.[12]

DIAGNOSTIC DIFFICULTY

Several medical, medication-induced, or substance-related causes of mania and depression have been identified (see Table 78–2 for causes of mania and Table 77–1 in Chapter 77 for causes of depression).[1,2] A complete medical, psychiatric, and medication history; physical examination; and laboratory testing are necessary to rule out any organic causes of mania or depression.[2] An accurate diagnosis is important because some psychiatric and neurologic disorders present with manic-like or depressive-like symptoms.[2,3] For example, attention-deficit/hyperactivity disorder and a manic episode have similar characteristics; thus individuals with bipolar disorder can be misdiagnosed and prescribed central nervous system stimulants.[5,21] Use of any substance that affects the central nervous system (e.g., alcohol, antidepressants, caffeine, central nervous system stimulants, hallucinogens, or marijuana) can worsen symptoms of mania or depression and decrease response to treatment.[2,10,22–24]

Another disease state that has a similar presentation to bipolar disorder is schizoaffective disorder. This disease is a mix between schizophrenia and bipolar disorder. Patients with schizoaffective disorder have mood episodes, but the distinguishing factor from bipolar disorder is that these patients experience psychosis even between mood episodes during periods of euthymia. Clinicians must rely on family members or others who know the patient well to determine if the patient is psychotic between mood episodes. It can be difficult for clinicians to obtain a full psychiatric history on patients, thus making schizoaffective disorder widely diagnosed. Schizoaffective disorder is treated with mood stabilizers and antipsychotics as maintenance therapy.

TABLE 78-2 Secondary Causes of Mania

Medical conditions that induce mania
• CNS disorders (brain tumor, strokes, head injuries, subdural hematoma, multiple sclerosis, systemic lupus erythematosus, temporal lobe seizures, Huntington disease)
• Infections (encephalitis, neurosyphilis, sepsis, human immunodeficiency virus)
• Electrolyte or metabolic abnormalities (calcium or sodium fluctuations, hyper- or hypoglycemia)
• Endocrine or hormonal dysregulation (Addison disease, Cushing disease, hyper- or hypothyroidism, menstrual-related or pregnancy-related or perimenopausal mood disorders)
Medications or drugs that induce mania
• Alcohol intoxication
• Drug withdrawal states (alcohol, α_2-adrenergic agonists, antidepressants, barbiturates, benzodiazepines, opiates)
• Antidepressants (MAOIs, TCAs, 5-HT and/or NE and/or DA reuptake inhibitors, 5-HT antagonists)
• DA-augmenting agents (CNS stimulants: amphetamines, cocaine, sympathomimetics; DA agonists, releasers, and reuptake inhibitors)
• Hallucinogens (LSD, PCP)
• Marijuana intoxication precipitates psychosis, paranoid thoughts, anxiety, and restlessness
• NE-augmenting agents (α_2-adrenergic antagonists, β-agonists, NE reuptake inhibitors)
• Steroids (anabolic, adrenocorticotropic hormone, corticosteroids)
• Thyroid preparations
• Xanthines (caffeine, theophylline)
• Over-the-counter weight loss agents and decongestants (ephedra, pseudoephedrine)
• Herbal products (St. John's wort)
Somatic therapies that induce mania
• Bright light therapy
• Sleep deprivation

CNS, central nervous system; DA, dopamine; 5-HT, serotonin; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; PCP, phencyclidine; TCA, tricyclic antidepressant.
Data from American Psychiatric Association,[1] and Kaplan and Sadock.[90]

CLINICAL PRESENTATION

1 The essential feature of bipolar spectrum disorders is a history of mania or hypomania that is not caused by any other medical condition, substance, or psychiatric disorder (see Table 78–2 for secondary causes of mania).[1,2] The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* of the American Psychiatric Association (APA) details the present understanding of mood disorders.[1] Bipolar disorder is divided into four subtypes based on the identification of specific mood episodes: bipolar I, bipolar II, cyclothymic disorder, and bipolar disorder not otherwise specified. See Table 78–3 for a definition of mood

TABLE 78-3 Mood Disorders Defined by Episodes

Disorder Subtype	Episode(s)[a]
Major depressive disorder, single episode	Major depressive episode
Major depressive disorder, recurrent	Two or more major depressive episodes
Bipolar disorder, type I[b]	Manic episode ± major depressive or mixed episode
Bipolar disorder, type II[c]	Major depressive episode + hypomanic episode
Dysthymic disorder	Chronic subsyndromal depressive episodes
Cyclothymic disorder[d]	Chronic fluctuations between subsyndromal depressive and hypomanic episodes (2 years for adults and 1 year for children and adolescents)
Bipolar disorder not otherwise specified	Mood states do not meet criteria for any specific bipolar disorder

[a]The length and severity of a mood episode and the interval between episodes varies from patient to patient. Manic episodes are usually briefer and end more abruptly than major depressive episodes. The average length of untreated manic episodes ranges from 4 to 13 months. Episodes can occur regularly (at the same time or season of the year) and often cluster at 12-month intervals. Women have more depressive episodes than manic episodes, whereas men have a more even distribution of episodes.
[b]For bipolar I disorder, 90% of individuals who experience a manic episode later have multiple recurrent major depressive, manic, hypomanic, or mixed episodes alternating with a normal mood state.
[c]Approximately 5%–15% of patients with bipolar II disorder will develop a manic episode over a 5-year period. If a manic or mixed episode develops in a patient with bipolar II disorder, the diagnosis is changed to bipolar I disorder.
[d]Patients with cyclothymic disorder have a 15%–50% risk of later developing a bipolar I or II disorder.
Data from American Psychiatric Association,[1] American Psychiatric Association,[2] and Goldberg and Harrow.[3]

TABLE 78-4 Evaluation and Diagnosis of Mood Episodes

Diagnosis Episode	Impairment of Functioning or Need for Hospitalization[a]	DSM-IV-TR Criteria[b]
Major depressive	Yes	>2-Week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms: • Depressed, sad mood (adults); can be irritable mood in children • Decreased interest and pleasure in normal activities • Decreased appetite, weight loss • Insomnia or hypersomnia • Psychomotor retardation or agitation • Decreased energy or fatigue • Feelings of guilt or worthlessness • Impaired concentration and decision making • Suicidal thoughts or attempts
Manic	Yes	>1-Week period of abnormal and persistent elevated mood (expansive or irritable), associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractible (poor attention) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Hypomanic	No	At least 4 days of abnormal and persistent elevated mood (expansive or irritable); associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Mixed	Yes	Criteria for both a major depressive episode and manic episode (except for duration) occur nearly every day for at least a 1-week period
Rapid cycling	Yes	>4 Major depressive or manic episodes (manic, mixed, or hypomanic) in 12 months

[a]Impairment in social or occupational functioning; need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.
[b]The disorder is not caused by a medical condition (e.g., hypothyroidism) or substance-induced disorder (e.g., antidepressant treatment, medications, electroconvulsive therapy).
Reprinted with permission from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed., Text Revision. Washington, DC: American Psychiatric Association, 2000:345–401.

disorders by type of episode. The mood states are further separated into four subcategories to differentiate the current or most recent mood episode: major depressive, manic, hypomanic, or mixed. See Table 78–4 for the evaluation and diagnostic criteria of mood episodes. A new concept of "bipolar spectrum disorder" has been suggested that broadens the diagnosis to include dysthymia, cyclothymia, drug-induced hypomania, and recurrent unipolar depression.[3,25] Bipolar disorder is a cyclic mood disorder, and patients may sequentially experience different types of episodes with or without a period of normal mood (euthymia) between. Persons with bipolar disorder can have mood fluctuations that continue for months, or after one episode they can sometimes go years without recurrence of any type of mood episode. Comorbid psychiatric disorders associated with bipolar disorder include but are not limited to the following: alcohol and substance abuse, personality disorders, and anxiety disorders such as panic disorder, social anxiety disorder, and obsessive-compulsive disorder.[1–3,10,22,24,26]

MAJOR DEPRESSIVE EPISODE

Bipolar depression is often underdiagnosed and is frequently misdiagnosed as major depressive disorder.[2,27] Approximately 95% of patients with bipolar disorder experience episodes of depression during their lifetime.[1,3] Compared with manic episodes, depressive episodes are more frequent, longer lasting, and occur more often in bipolar II than in bipolar I disorder.[3,28] Over a person's lifetime, depressive episodes can account for up to 80% of all mood episodes. Recurrent depressive episodes are more common in women compared to men.[3] In bipolar depression, patients have an increased suicide risk and often have mood lability, hypersomnia, low energy, psychomotor retardation, cognitive impairment, anhedonia, decreased sexual activity, slowed speech, carbohydrate craving, and weight gain (also called atypical depressive features).[3,28,29] Delusions, hallucinations, and suicide attempts are more common in bipolar depression than in unipolar depression.[3]

MANIC EPISODE

For a diagnosis of mania, the symptoms must last at least 1 week, the mood must be elevated (expansive or irritable), and there must be an impairment in functioning.[1] Acute mania usually begins abruptly, and symptoms escalate over several days. Common symptoms of mania include grandiosity, decreased need for sleep or food, pressured speech, flight of ideas (racing thoughts), distractibility, increased activity, poor judgment, and involvement in pleasurable activities with potentially negative consequences.[1] Patients with acute mania often have psychotic symptoms, thus some patients are incorrectly diagnosed as having schizophrenia.[10] Mania symptoms that can resemble paranoid schizophrenia are bizarre behavior, hallucinations, and paranoid or grandiose delusions. Seasonal changes,

stressors, sleep deprivation, antidepressants, central nervous system stimulants, or bright light can precipitate a manic episode.

HYPOMANIC EPISODE

Hypomania is a less severe form of mania, and by definition does not cause a marked impairment in social or occupational functioning, and no delusions or hallucinations are present.[1,3] Patients with hypomania often do not seek treatment until they have a depressive episode, thus hypomania may not be recognized or reported.[2] Symptoms found in hypomanic episodes are similar to those of cocaine- or antidepressant-induced mood disorders; thus the differential diagnosis should rule out any substance-induced or medical conditions that present with elevated mood.[24] Hypomanic states should be closely monitored, because 5% to 15% of patients can rapidly switch to a manic episode.[3]

MIXED EPISODE

Bipolar "mixed episode" (previously known as mixed state, dysphoric mania, or depressive mania) is defined as the simultaneous occurrence of manic and depressive symptoms.[1,3] Mixed mood states occur in up to 40% of all episodes and are more common in younger and older patients and in females.[3] Mixed episodes are often difficult to diagnose and treat because of the fluctuating clinical presentation. Patients with mixed states often have comorbid alcohol and substance abuse, severe anxiety symptoms, a higher suicide rate, and a poorer prognosis.[3,24]

COURSE OF ILLNESS

1 Bipolar disorder is frequently not recognized and treated for many years because of its fluctuating course and episodic mood states.[2,3,10] The onset of bipolar disorder is rare before puberty, but its incidence increases during late adolescence and into early adulthood (usually between the ages of 15 and 30 years).[1] The average age of onset of a first manic episode is 21 years for both men and women.[2] Bipolar disorder affects an estimated 1% of children and adolescents and is often harder to recognize, diagnose, and treat than in a typical adult patient.[1,2,23,30] Before the onset of mania, adolescents can exhibit irritability, hyperactivity, impulsivity, emotional lability, poor judgment, marked anxiety, insomnia, depression, and psychosis.[1,11,21] The first episode in females is more likely to be a major depressive episode, whereas males are more likely to first experience a manic episode.[1,2] Women are more likely to have mixed states, depressive episodes, and rapid cycling compared with men.[1,2] Onset of manic episodes after the age of 60 years is rare and is likely caused by a medical or neurologic condition (e.g., stroke, tumor, or dementia), medications, or substance use.[2]

The kindling theory is used to explain why bipolar disorder progresses over one's life and why preventative treatment is imperative. Episodes can become longer in duration and more frequent with aging.[2] Usually there is a period of normal functioning between episodes, but approximately 20% to 30% of patients with bipolar I disorder and 15% with bipolar II disorder have no period of euthymia because of mood lability, residual mood symptoms, or a direct switch to the opposite polarity.[1]

Rapid cycling (more than four mood episodes per year) is more common in females and occurs in approximately 10% to 20% of bipolar I and II disorder patients.[2,3,16,23] Frequent and severe episodes of depression appear to be the most common hallmark of rapid cycling. Use of alcohol, stimulants, antidepressants, sleep deprivation, hypothyroidism, and seasonal changes can play a role in rapid cycling.[3,23,31] Seasonal patterns of mania in the summer and depression during the winter have been observed. Rapid-cycling patients have a poorer long-term prognosis and often require combination therapies.[3]

Fluctuations in hormones and neurotransmitters during the luteal phase of the menstrual cycle, postpartum period, and during perimenopause (starting ~10 years before menopause) can precipitate mood changes and increase cycling.[1,16,19] Women with bipolar I disorder are at greater risk for relapse into mania or depression during the postpartum period.[2] If a severe mood episode occurs postpartum, there is an increased risk for recurrences during subsequent postpartum periods.[2]

Alcohol and substance abuse is common among patients with bipolar disorder and can have a significant impact on the age of onset, course of the illness, and response to treatment.[3,10,22] Alcohol and drug abuse or dependence has been reported in 46% and 41% of bipolar patients, respectively.[2,10] Patients with substance use disorders are more likely to have an earlier onset of their illness, mixed states, higher rates of relapse, a poorer response to treatment, comorbid personality disorders, increased suicide risk, and more psychiatric hospitalizations.[3] Bipolar patients often self-medicate with substances such as alcohol or cocaine during episodes, resulting in further impairment of judgment, poor impulse control, treatment nonadherence, and a worsening of the clinical course.[2,3,24]

More than one-half (55%–65%) of bipolar I patients have some degree of functional disability after the onset of their illness, and approximately 10% to 20% of bipolar patients have severe impairment in their psychosocial and occupational functioning.[2,3,32] In a 1-year longitudinal study in 258 bipolar patients, two-thirds had four or more mood episodes a year despite comprehensive pharmacologic treatment, and approximately 33.2% of the year was spent being depressed compared to 10.8% of the time in a manic phase.[32]

Compared with the general population, individuals with bipolar disorder have a 2.3-times higher mortality rate. Suicide attempts occur in up to 50% of patients with bipolar disorder, and approximately 10% to 19% of individuals with bipolar I disorder commit suicide.[1–3,29] Studies suggest patients with bipolar II disorder have more suicide attempts than bipolar I patients.[29] Suicidal ideation and attempts are most likely to occur in a depressive or mixed state and in patients with personality disorders, psychotic features, and/or a comorbid alcohol- and substance-use disorder.[2,3,33] Acutely manic or depressed patients can need hospitalization because they are suicidal, have violent or aggressive behavior, or lack appropriate judgment and insight.[2] Accidental deaths are more frequent during manic episodes when the person has grandiosity, hallucinations, or delusions that result in risk-taking behaviors.[2] In addition, bipolar patients have a higher mortality from endocrine, respiratory, and cardiovascular disease that can be related to higher rates of obesity, smoking, alcohol and substance abuse, infections, and lack of medical care.[2]

The best predictor for level of functioning during a person's lifetime is adherence with medication treatment. Medication discontinuation occurs in up to 50% of patients secondary to intolerance of drug-induced side effects.[34] Failure to recognize the disorder, reluctance to acknowledge it, or poor adherence with treatment are reasons an estimated two-thirds of patients with bipolar disorder do not receive appropriate treatment. Nonadherence with pharmacologic treatment and substance abuse are major factors in relapse and hospitalizations.[2,3]

TREATMENT

DESIRED OUTCOME

3 The desired outcome for bipolar disorder is to prevent an acute manic, hypomanic, or depressive episode, to maintain good functioning, and to prevent further episodes of mania or depression.[2,3]

TABLE 78-5 General Principles for the Management of Bipolar Disorder

Goals of treatment

- Eliminate mood episode with complete remission of symptoms (i.e., acute treatment)
- Prevent recurrences or relapses of mood episodes (i.e., continuation phase treatment)
- Return to complete psychosocial functioning
- Maximize adherence with therapy
- Minimize adverse effects
- Use medications with the best tolerability and fewest drug interactions
- Treat comorbid substance use and abuse
- Eliminate alcohol, marijuana, cocaine, amphetamines, and hallucinogens
- Minimize nicotine use and stop caffeine intake at least 8 hours prior to bedtime
- Avoidance of stressors or substances that precipitate an acute episode

Monitor for

- Mood episodes: document symptoms on a daily mood chart (document life stressors, type of episode, length of episode, and treatment outcome); monthly and yearly life charts are valuable for documenting patterns of mood cycles
- Medication adherence (missing doses of medications is a primary reason for nonresponse and recurrence of episodes)
- Adverse effects, especially sedation and weight gain (manage rapidly and vigorously to avoid noncompliance)
- Suicidal ideation or attempts (suicide completion rates with bipolar I disorder are 10%–15%; suicide attempts are primarily associated with depressive episodes, mixed episodes with severe depression or presence of psychosis)

Data from American Psychiatric Association,[2] Goodnick,[10] and Suppes et al.[42]

The general principles and goals for the management of bipolar disorder are found in Table 78–5.

GENERAL APPROACH TO TREATMENT

4 Treatment of bipolar disorder must be individualized because the clinical presentation, severity, and frequency of episodes vary widely among patients. Treatment approaches should include both nonpharmacologic and pharmacologic strategies.[3] Patients and family members should be educated about bipolar disorder (e.g., symptoms, causes, and course) and treatment options. Long-term adherence to treatment is the most important factor in achieving stabilization of the disorder.

5 The treatment of bipolar disorder can vary depending on what type of episode the patient is experiencing. Once diagnosed with bipolar disorder, patients should remain on a mood stabilizer (e.g., lithium, valproate) for their lifetime. During acute episodes, medications can be added and then tapered once the patient is stabilized and euthymic. For example, when treating a patient for mania with psychotic features, the patient should be on a mood stabilizer and an antipsychotic. If the antipsychotic is the patient's maintenance therapy, the dose should be increased or perhaps the medication should be changed altogether if the patient goes into a manic episode. If treating a patient for a severe depressive episode, a clinician may need to maximize the dose of the mood stabilizer or add another medication (e.g., quetiapine).

Nonpharmacologic Therapy

The basics of nonpharmacologic approaches should address issues of adequate nutrition, sleep, exercise, and stress reduction.[3] Sleep deprivation, high stress, and deficiencies in dietary essential amino acids, fatty acids, vitamins, and minerals can exacerbate mood episodes and result in poorer outcomes.[3] Mood charting is an effective strategy in detecting early signs and symptoms of mania and depression. Another effective treatment is to combine medications with adjunctive psychoeducational programs, supportive counseling, insight-oriented psychotherapy (individual or group), couples or family therapy, cognitive behavioral therapy, and communication enhancement training.[2,3,10,35]

Most communities have self-help, support groups, and mental health organizations that provide information, educational materials, and counseling. For public information, individuals can contact the Depression and Bipolar Support Alliance at 800–826–3632 and *www.dbsalliance.org*; the National Alliance on Mental Illness (NAMI) at 800–950–6264 (help line) and *www.nami.org*; Mental Health America (National Mental Health Association) 800–969–6642 (resource center) and *www.nmha.org*; and the National Institute of Mental Health at 866–615–6464 and *www.nimh.nih.gov*.[2]

Several nonpharmacologic treatment strategies (e.g., electroconvulsive therapy [ECT], high-intensity bright light therapy, phase-advanced sleep schedule, and partial or complete sleep deprivation) have been used in the treatment of bipolar disorder.[2,3] The use of ECT for the treatment of severe episodes of mania, depression, psychotic features (e.g., hallucinations or delusions), mixed episodes, or rapid cycling should be considered for those patients who do not respond to medications.[2,3] Repetitive transcranial magnetic stimulation (rTMS) has been reported to be effective in bipolar disorder. Most data include the use of rTMS as augmentation in drug-resistant bipolar depression.[36] A small amount of data support the use of rTMS in treating mania and for maintenance treatment in bipolar depression.[37,38] Vagus nerve stimulation (VNS) may also have a role in treatment-resistant rapid-cycling bipolar disorder.[39] More studies are needed to assess the role of VNS in bipolar disorder.

Pharmacologic Therapy

5 Pharmacotherapy is crucial for the acute and maintenance treatment of bipolar disorder and includes lithium, valproate, carbamazepine, lamotrigine, first- and second-generation antipsychotics, and adjunctive agents such as antidepressants and benzodiazepines. General treatment guidelines for the acute treatment of mood episodes in patients with bipolar I disorder are found in Table 78–6.

Product information, dosing and administration, and clinical use for agents used in the treatment of bipolar disorder are found in Table 78–7.

5 The term *mood stabilizer* is often used to describe the class of medications used in the treatment of bipolar disorder, but this may not be accurate as some medications are more effective for acute mania, some for the depressive episode, and others for the maintenance phase.[40] Lithium, valproate (or divalproex sodium), extended-release carbamazepine, aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of acute mania in bipolar disorder; only lithium, divalproex sodium, aripiprazole, olanzapine, and lamotrigine are approved for the maintenance treatment of bipolar disorder. Quetiapine is the only monotherapy antipsychotic that is FDA approved for bipolar depression. Lithium is the drug of choice for bipolar disorder with euphoric mania, whereas valproate has better efficacy for mixed states, irritable/dysphoric mania, and rapid cycling compared with lithium.[2]

Combination therapies (e.g., lithium plus valproate or carbamazepine; lithium or valproate plus SGA) can provide better acute response and long-term prevention of relapse and recurrence than monotherapy in some bipolar patients, particularly those with mixed states or rapid cycling.[2,40] The majority of patients hospitalized for an acute episode will be on combination therapy.

TABLE 78-6 Algorithm and Guidelines for the Acute Treatment of Mood Episodes in Patients with Bipolar I Disorder

Acute Manic or Mixed Episode

General guidelines

Assess for secondary causes of mania or mixed states (e.g., alcohol or drug use)
Discontinue antidepressants
Taper off stimulants and caffeine if possible
Treat substance abuse
Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy

Hypomania

First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium,[a] valproate,[a] carbamazepine,[a] or SGAs
Consider adding a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed
Alternative medication treatment options: oxcarbazepine
Second, if response is inadequate, consider a two-drug combination:
- Lithium[a] **plus** an anticonvulsant or an SGA
- Anticonvulsant **plus** an anticonvulsant or SGA

Mania

First, two or three drug combinations: lithium,[a] valproate,[a] or SGA **plus** a benzodiazepine (lorazepam or clonazepam) and/or antipsychotic for short-term adjunctive treatment of agitation or insomnia; lorazepam is recommended for catatonia
Do not combine antipsychotics
Alternative medication treatment options: carbamazepine[a]; if patient does not respond or tolerate, consider oxcarbazepine
Second, if response is inadequate, consider a three-drug combination:
- Lithium[a] **plus** an anticonvulsant **plus** an antipsychotic
- Anticonvulsant **plus** an anticonvulsant **plus** an antipsychotic

Third, if response is inadequate, consider ECT for mania with psychosis or catatonia[d]; or add clozapine for treatment refractory illness

Acute Depressive Episode

General guidelines

Assess for secondary causes of depression (e.g., alcohol or drug use)
Taper off antipsychotics, benzodiazepines or sedative-hypnotic agents if possible
Treat substance abuse
Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy

Mild to moderate depressive episode

First, initiate and/or optimize mood stabilizing medication: lithium[a] or quetiapine
Alternative anticonvulsants: lamotrigine[b] valproate,[a] antipsychotics: fluoxetine/olanzapine combination

Severe depressive episode

First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium[a] or quetiapine
Alternative fluoxetine/olanzapine combination
If psychosis is present, initiate an antipsychotic in combination with above
Do not combine antipsychotics
Alternative anticonvulsants: lamotrigine[b] valproate,[a]
Second, if response is inadequate, consider carbamazepine[a] or adding antidepressant
Third, if response is inadequate, consider a three drug combination:
- Lithium **plus** lamotrigine[b] **plus** an antidepressant
- Lithium **plus** quetiapine **plus** antidepressant

Fourth, if response is inadequate, consider ECT for treatment-refractory illness and depression with psychosis or catatonia[d]

ECT, electroconvulsive therapy; MAOI, monoamine oxidase inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; SGA, second-generation antipsychotic, SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

[a]Use standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

[b]Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated up to decrease adverse effects if used for maintenance therapy of bipolar I disorder. Lamotrigine may be initiated during acute treatment with plans to transition to this medication for long-term maintenance. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (i.e., lamotrigine doses must be halved from standard dosing titration).

[c]Controversy exists concerning the use of antidepressants, and they are often considered third line in treating acute bipolar depression, except in patients with no recent history of severe acute mania or potentially in bipolar II patients.

[d]ECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, and benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

Data from American Psychiatric Association,[2] CANMAT & ISBD,[41] and Suppes et al.[42]

Several guidelines and algorithms have been published regarding the treatment of bipolar disorder, and these are generally based on the best available data and the clinical consensus of experts. The Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders (ISBD) published updated treatment guidelines in 2009.[41] A new edition of *Practice Guideline for the Treatment of Patients with Bipolar Disorder* published by the APA is expected to be released in the near future.[2] The APA guidelines address the diagnosis, clinical course, epidemiology, and treatment strategies for adults but are not intended to be used as a standard of psychiatric care. The Texas Department of Mental Health and Mental Retardation has developed and implemented algorithms in the public mental health system to improve treatment outcomes with bipolar I disorder.[42] Several other states have also adopted and implemented programs similar to the Texas algorithm project. The Texas algorithm project data are in the process of being updated. The last updates posted are from 2007. In addition, an international task force of the World Federation of Societies of Biological Psychiatry (WFSBP) has published guidelines for the treatment of bipolar depression and mania.[43,44] The WFSBP mania guidelines were updated in 2009, but bipolar depression (2002) and maintenance (2003) guidelines have yet to be updated.

Based on the CANMAT and ISBD guidelines and available research, an example treatment algorithm and guidelines for acute mood episodes in adult patients with bipolar I disorder are listed in Table 78–6.[41] Because newer anticonvulsants, SGAs, and combination therapies are under investigation for bipolar disorder, published guidelines, algorithms, and decision trees can quickly become out of date as new scientific knowledge evolves. Selection of treatments for acute mood episodes (e.g., manic or mixed, depressive, or rapid cycling) and for maintenance strategies to prevent relapses of mood episodes should be individualized. Treatment plans should be based on patient-specific characteristics, comorbid psychiatric and medical conditions, and avoidance of drug interactions and adverse effects.[2]

There are few controlled studies in children and adolescents with bipolar disorder, thus little is known about the long-term efficacy and safety of specific agents or for combination therapies in this population.[5,30] Lithium, valproic acid, and carbamazepine are all used in pediatric bipolar disorder. Lithium is the only medication

TABLE 78-7 Products, Dosage and Administration, and Clinical Use of Agents Used in the Treatment of Bipolar Disorder

Generic Name	Trade Name	Dosage and Administration	Clinical Use
Lithium salts: FDA approved for bipolar disorder			
Lithium carbonate[a,c]	Eskalith Eskalith CR Lithobid	900–2,400 mg/day in 2–4 divided doses, preferably with meals. There is wide variation in the dosage needed to achieve therapeutic response and trough serum lithium concentration (i.e., 0.6–1.2 mEq/L (mmol/L) for maintenance therapy and 1.0–1.2 mEq/L (mmol/L) for acute mood episodes taken 8–12 hours after the last dose).	Use alone or in combination with other drugs (e.g., valproate, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment.
Lithium citrate[a,c]	Cibalith-S		
Anticonvulsants: FDA-approved for bipolar disorder			
Divalproex sodium[a]	Depakote Depakote ER	750–3,000 mg/day (20–60 mg/kg/day) given once daily or in divided doses for delayed-release divalproex or valproic acid.	Use alone or in combination with other drugs (e.g., lithium, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment.
Valproic acid[a]	Stavzor	A loading dose of divalproex (20–30 mg/kg/day) can be given, then 20 mg/kg per day and titrated to a serum concentration of 50–125 mcg/mL (346–866 µmol/L) or clinical response.	Use caution when combining with lamotrigine because of potential drug interaction.
Lamotrigine[c]	Lamictal	50–400 mg/day in divided doses. Dosage should be slowly increased (e.g., 25 mg/day for 2 wk, then 50 mg/day for wk 3 and 4, then 50-mg/day increments at weekly intervals up to 200 mg/day).	Use alone or in combination with other drugs (e.g., lithium, carbamazepine) for long-term maintenance treatment for bipolar I disorder.
Carbamazepine	Equetro[a]	200–1,800 mg/day in 2–4 divided doses. Dosage should be slowly increased according to response and adverse effects (e.g., 100–200 mg twice daily and increase by 200 mg/day at weekly intervals). Dose can be increased rapidly for inpatients. Extended-release tablets should be swallowed whole and not be broken or chewed.	Use alone or in combination with other medications (e.g., lithium, valproate, antipsychotics) for the acute and long-term maintenance treatment of mania or mixed episodes for bipolar I disorder. APA guidelines recommend reserving it for patients unable to tolerate or who have inadequate response to lithium or valproate.
Anticonvulsants: Not FDA approved for bipolar disorder			
Carbamazepine	Tegretol, Epitol Tegretol-XR Carbatrol	200–1,800 mg/day in 2–4 divided doses. Dosage should be slowly increased according to response and adverse effects (e.g., 100–200 mg twice daily and increase by 200 mg/day at weekly intervals). Dose can be increased rapidly for inpatients. Administer conventional tablets and suspension with meals. Extended-release tablets should be swallowed whole and not be broken or chewed. Carbatrol capsules can be opened and contents sprinkled over food.	Use alone or in combination with other medications (e.g., lithium, valproate, anti-psychotics) for the acute and long-term maintenance treatment of mania or mixed episodes for bipolar I disorder. APA guidelines recommend reserving it for patients unable to tolerate or who have inadequate response to lithium or valproate.
Valproic acid Valproate sodium	Depakene Depacon	750–3,000 mg/day (20–60 mg/kg/day) given once daily or in divided doses for delayed-release divalproex or valproic acid. A loading dose of divalproex (20–30 mg/kg/day) can be given, then 20 mg/kg/day and titrated to a serum concentration of 50–125 mcg/mL (346–866 µmol/L) or clinical response.	Use alone or in combination with other drugs (e.g., lithium, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment. Use caution when combining with lamotrigine because of potential drug interaction.
Oxcarbazepine	Trileptal	300–1,200 mg/day in two divided doses. Dosage should be slowly adjusted up and down according to response and adverse effects (e.g., 150–300 mg twice daily and increase by 300–600 mg/day at weekly intervals). Dose can be increased rapidly for inpatients.	Use after patients have failed treatment with carbamazepine or have intolerable side effects. May have fewer adverse effects and be better tolerated than carbamazepine.
Atypical antipsychotics: FDA-approved for bipolar disorder			
Aripiprazole[a,c]	Abilify	10–30 mg/day once daily.	May be used in combination with lithium, valproate, or carbamazepine for the acute treatment of mania or mixed states (primarily with psychotic features) for bipolar I disorder.
Olanzapine[a,c]	Zyprexa Zyprexa Zydis	5–20 mg/day once daily or in divided doses.	
Olanzapine and Fluoxetine[b]	Symbyax	6–12 mg olanzapine and 25–50 mg fluoxetine daily.	
Quetiapine[a,c]	Seroquel	50–800 mg/day in divided doses or once daily when stabilized.	
Risperidone[a]	Risperdal Risperdal M-Tab	0.5–6 mg/day once daily or in divided doses.	
Ziprasidone[a]	Geodon	40–160 mg/day in divided doses. Administer with food.	
Benzodiazepines		Dosage should be slowly adjusted up and down according to response and adverse effects.	Use in combination with other medications (e.g., antipsychotics, lithium, valproate) for the acute treatment of mania or mixed episodes. Use as a short-term adjunctive sedative-hypnotic agent.

FDA approved agents may be used as monotherapy in various phases of the illness as noted by.[a,b,c]

[a]FDA approved for acute mania.

[b]FDA approved for acute bipolar depression.

[c]FDA approved for maintenance.

Data from American Psychiatric Association,[2] Goldberg and Harrow,[3] Goodnick,[10] Manji et al.,[12] White,[18] and CANMAT & ISBD.[41]

approved for children older than 12 years of age as a mood stabilizer.[45] Valproate data are limited. One double-blind, randomized, placebo-controlled trial of extended-release divalproex showed similar results to placebo for mania or mixed episodes in children and adolescents.[46] Risperidone and aripiprazole are FDA approved for pediatric bipolar mania. Olanzapine, quetiapine, and ziprasidone have support for their use by an FDA advisory panel for pediatric acute mania, but do not yet have FDA approval.[47] The advisory panel recommended that the FDA approve quetiapine in patients aged 10 to 17 years during a manic episode, olanzapine as a second-line therapy in young patients with manic or mixed episodes, and ziprasidone in patients aged 10 to 17 years as a second-line therapy in patients with manic or mixed episodes.[47] Long-term data are still needed for all of these agents. Published guidelines for treatment of bipolar disorder in children and adolescents include the *Practice Parameters for the Assessment and Treatment of Children and Adolescents with Bipolar Disorder* by the American Academy of Child and Adolescent Psychiatry.[5]

Specific Pharmacologic Therapies

Lithium Lithium was first used in 1949 as a treatment for mania and was approved in 1972 in the United States for the treatment of acute mania and for maintenance therapy. Despite numerous investigations into the biologic and clinical properties of lithium, there is no unified theory for its mechanism of action.[6,10,13,48] Chronic lithium administration may modulate gene expression and have neuroprotective effects. Lithium has unique pharmacokinetics because it is a monovalent cation. Lithium is rapidly absorbed, is widely distributed with no protein binding, is not metabolized, and is excreted unchanged in the urine and in other body fluids.[49] Lithium requires regular assessment of renal and thyroid functioning and lithium blood level monitoring to minimize adverse effects.[3]

Efficacy Lithium was the first established mood stabilizer, and is still considered a first-line agent for acute mania, acute bipolar depression, and continuation treatment of bipolar I and II disorders.[41] Early placebo-controlled studies with lithium reported up to a 78% response rate in aborting an acute manic or hypomanic episode, but more recent studies suggest a slower onset of action and a more moderate effectiveness when compared with other agents.[2,3,50] Lithium has displayed efficacy in acute mania trials similar to that of valproate, carbamazepine, risperidone, olanzapine, chlorpromazine, and other first-generation antipsychotics (FGAs).[2] In placebo-controlled studies in bipolar depression, lithium has been found to have efficacy, but there can be a 6- to 8-week delay for its antidepressant effects.[2] Lithium is more effective for pure or elated (classic) mania, and can be less effective for mania with psychotic features, mixed episodes, rapid or continuous cycling, alcohol and drug abuse, and in organic-induced mood states.[2,3,51]

Long-term lithium therapy is more effective in patients with fewer prior episodes, with a history of euthymia or good functioning between episodes, and with a family history of bipolar illness with a positive response to lithium. Lithium produces a prophylactic response in up to two-thirds of patients and reduces suicide risk by 8- to 10-fold.[2,50–52]

Patients maintained on standard serum concentrations of lithium (0.8–1.0 mEq/L [mmol/L]) may have fewer relapses than patients maintained on lower serum concentrations (0.4–0.6 mEq/L [mmol/L]).[2,3] Abrupt discontinuation or noncompliance with lithium therapy can increase the risk of relapse.[2,3] Discontinuation-induced refractoriness has been reported in approximately one-fifth of patients who previously were stabilized on lithium.[2,3]

Lithium augmentation of carbamazepine, lamotrigine, and valproate can improve treatment response in bipolar I disorder.[2,53] Concomitant use of lithium with valproate or carbamazepine appears to be well tolerated but can increase the risk of sedation, weight gain, gastrointestinal complaints, and tremor.

Lithium is frequently combined with either FGAs or SGAs for treatment of euphoric acute mania with psychotic features. Case reports of neurotoxicity (e.g., delirium, cerebellar dysfunction, extrapyramidal symptoms, and severe tremors) have been published in elderly patients receiving lithium and FGAs.[49] Combining lithium with calcium channel blockers is not recommended because of reports of neurotoxicity and severe bradycardia with verapamil or diltiazem.[49] Acute neurotoxicity and delirium have been reported in patients receiving ECT with lithium (even at reduced dosages); therefore, lithium should be withdrawn and discontinued at least 2 days before ECT and should not be resumed until 2 to 3 days after the last treatment.

Adverse Effects Approximately 35% to 93% of patients treated with lithium will experience adverse effects. These are divided into those that occur early in therapy but are generally innocuous and transient, those that occur with long-term therapy and are usually not dose related, and toxic effects that occur with high serum concentrations.[2,49]

Initial side effects are often dose related and are worse at peak serum concentrations (1–2 hours postdose).[2] Standard approaches for minimizing adverse effects include lowering the dose, taking smaller doses with food, using extended-release products, and trying once-daily dosing at bedtime.[2] Gastrointestinal distress (e.g., nausea, vomiting, dyspepsia, and diarrhea) can be minimized by the standard approaches or by adding antacids or antidiarrheal agents.[2] Diarrhea can sometimes be managed by switching from tablet or capsule formulation to liquid formulation. Diarrhea produced by lithium is commonly an osmotic diarrhea, and therefore switching to a formulation that clears the gut quickly can ameliorate symptoms. Muscle weakness and lethargy develop in about 30% of patients, but these symptoms are usually transient. Polydipsia with polyuria and nocturia occurs in up to 70% of patients and can be managed by changing to once-daily bedtime dosing.

As many as 40% of patients complain of headache, memory impairment, confusion, poor concentration, and impaired motor performance.[10] A fine hand tremor can be evident in up to 50% of patients. Stress, concomitant use of antidepressants or antipsychotics, caffeine, sympathomimetics, and impending toxicity can exacerbate the tremor. Strategies to reduce the tremor include standard approaches (e.g., switch to long-acting preparation, lower dose if possible) or adding a β-adrenergic antagonist (e.g., propranolol 20–120 mg/day).

Lithium reduces the kidney's ability to concentrate urine and can cause a nephrogenic diabetes insipidus characterized by low urine specific gravity and a low osmolality polyuria (urine volumes greater than 3 L/day).[2,49] Lithium-induced nephrogenic diabetes insipidus is treated with loop diuretics, thiazide diuretics, or triamterene. If a thiazide diuretic is used (e.g., hydrochlorothiazide 50 mg/day), lithium doses should be decreased by 50%, and potassium levels should be monitored.[2] Amiloride, a potassium-sparing diuretic, has weaker natriuretic effects than thiazides and appears to be relatively safe with minimal effect on lithium clearance. Potassium supplements have been suggested as another treatment for lithium-induced polyuria.[10] Fluid restriction is not recommended because dehydration increases the risk of lithium toxicity. If edema occurs, treatment approaches include lowering sodium intake or using a diuretic (e.g., spironolactone); close monitoring for lithium toxicity is necessary because these treatments often increase lithium concentrations.

Patients on long-term lithium therapy have a 10% to 20% risk of developing morphologic renal changes (e.g., glomerular sclerosis,

tubular atrophy, and interstitial nephritis) that is associated with impairment of water resorption and increased serum creatinine concentrations.[2] Lithium rarely causes nephrotoxicity if patients are maintained on the lowest effective dose, if once-daily dosing is used, if adequate hydration is maintained, and if toxicity is avoided.[10] Lithium should be avoided in patients with preexisting renal disease unless there is frequent monitoring.

Lithium is concentrated in the thyroid gland, interferes with thyroid hormone synthesis, and can induce the formation of thyroid antibodies.[49] Up to 30% of patients on maintenance lithium therapy develop transiently elevated thyroid-stimulating hormone concentrations, and 5% to 35% of patients develop a goiter and/or hypothyroidism.[2] Lithium-induced hypothyroidism is not dose-related, is observed 10 times more frequently in women (particularly in those with rapid cycling), and usually occurs after 6 to 18 months of therapy.[2] Hypothyroidism does not require discontinuation of lithium, because exogenous thyroid hormone (i.e., levothyroxine) can be added to the regimen. When lithium is discontinued, the need for exogenous thyroid hormone should be reassessed, because hypothyroidism can be reversible.

Lithium can cause a variety of benign and reversible cardiac effects, particularly T-wave flattening or inversion (in up to 30% of patients), atrioventricular block, and bradycardia.[2,10,49] Lithium rarely causes myocarditis, sinus node dysfunction, or sinoatrial block but can aggravate ventricular arrhythmias and atrial premature contractions. If a patient has significant preexisting cardiac disease, consultation with a cardiologist and an electrocardiogram is recommended at baseline and during lithium therapy.

Other late-appearing lithium side effects include benign reversible leukocytosis and a variety of dermatologic effects (e.g., acne and acneiform eruptions, alopecia, exacerbation of psoriasis, pruritic dermatitis, maculopapular rashes, and folliculitis).[3,12] Weight gain is common (~20% of patients gain >10 kg [22 lb]) and can be related to fluid retention, the consumption of high-calorie beverages as a result of polydipsia, or to a decreased metabolic rate because of hypothyroidism.[10,51] Decreased libido, sexual dysfunction, dry mouth, alterations in taste, changes in glucose tolerance, hypercalcemia, and hyperparathyroidism have been reported.[2,10,49] Severe neurologic disturbances such as coarse hand tremors, ataxia, slurred speech, myasthenia gravis, extrapyramidal syndrome, pseudotumor cerebri, and papilledema are occasionally observed.

Lithium is an extremely toxic drug if accidentally or intentionally taken in overdose. Lithium toxicity can occur with blood levels greater than 1.5 mEq/L (mmol/L), but elderly patients can have symptoms of toxicity at therapeutic levels.[2] Severe lithium intoxication occurs when concentrations are higher than 2.0 mEq/L (mmol/L), and there is a worsening in several key symptoms: *gastrointestinal* (e.g., vomiting, diarrhea, or incontinence); *coordination* (e.g., severe fine to coarse hand tremor, unstable gait, slurred speech, and muscle twitching); and *cognition* (e.g., poor concentration, drowsiness, disorientation, apathy, and coma).[2] Several reports of seizures, cardiac dysrhythmia, permanent neurologic impairments with ataxia and deficits in memory, and kidney damage with reduced glomerular filtration rate have been reported after lithium intoxication.[2]

Situations that predispose patients to lithium toxicity include sodium restriction, dehydration, vomiting, diarrhea, and drug interactions that decrease lithium clearance. Heavy exercise, sauna baths, hot weather, and fever can promote sodium loss. Patients should be cautioned to maintain adequate sodium and fluid intake (2.5–3 quarts [~2.5 to 3 L] per day of fluids) and to avoid the excessive use of coffee, tea, cola, and other caffeine-containing beverages and alcohol.

If lithium toxicity is suspected, the person should go to an emergency room to be monitored, and lithium should be discontinued.[2] Gastric lavage and intravenous fluids can be needed, and the patient should be monitored for fluid balance, renal and electrolyte status, and neurologic changes. In cases of overdose with sustained-release lithium products, the development and duration of toxicity can be prolonged.[2] When lithium concentrations are above 3.5 to 4 mEq/L (mmol/L), intermittent hemodialysis (12 hours on and 12 hours off) can be started and continued until the lithium concentration is below 1 mEq/L (mmol/L) when taken 12 hours after the last dialysis. Hemodialysis is generally required when serum lithium levels are above 4 mEq/L (mmol/L) for patients on long-term treatment, and greater than 6 to 8 mEq/L (mmol/L) after acute poisoning.[2] Rebound increases in serum lithium concentrations can occur 5 to 8 hours after dialysis, thus repeat dialysis can be needed.[2]

Drug–Drug Interactions Thiazide diuretics, nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors, angiotensin-converting enzyme inhibitors, and salt-restricted diets can elevate lithium levels.[2] Neurotoxicity can occur when lithium is combined with carbamazepine, diltiazem, losartan, methyldopa, metronidazole, phenytoin, and verapamil.[2,49] Analgesics such as acetaminophen or aspirin and loop diuretics are less likely to interfere with lithium clearance. Caffeine and theophylline can enhance the renal elimination of lithium. Because lithium has no effect on hepatic metabolizing enzymes, it has fewer drug–drug interactions compared with carbamazepine, oxcarbazepine, and valproate.

Dosing and Administration Lithium dosing depends on the patient's age and weight, tolerance to adverse effects, and the acuity of the illness. Dosing is generally titrated up to achieve steady-state serum lithium concentrations of 0.6 to 1.2 mEq/L (mmol/L).[2] Lithium therapy is usually initiated with low to moderate doses (600 mg/day) for prophylaxis and higher doses (900–1,200 mg/day) for acute mania, using a 2- to 3-times daily dosing regimen.[2,49] Immediate-release lithium preparations should be given in two or three divided daily doses, whereas extended-release products can be given once or twice daily. In clinical practice many clinicians dose the immediate-release and extended-release preparations once daily. It can be best to initially begin a patient on divided dosing, but once stabilized many patients are able to switch to once daily dosing without decompensating.

Lithium levels are considered to be at steady state at approximately day 5, and serum samples should be drawn 12 hours post-dose. Once a desired serum concentration has been achieved, levels should be drawn in 2 weeks and then if stable every 3 to 6 months or as clinically indicated. Maintenance lithium serum concentrations are usually measured every 3 months, but can be adjusted to every 6 months for stabilized patients, and every 1 to 2 months for patients with frequent mood episodes.[2] Lithium clearance rates increase by 50% to 100% during pregnancy and return to normal postpartum; thus lithium levels should be determined monthly during pregnancy and weekly the month before delivery. At delivery, rapid fluid changes can significantly increase lithium levels, thus a reduction to prepregnancy lithium doses and adequate hydration are recommended.[2]

The recommended guidelines for baseline and routine laboratory testing for lithium are listed in Table 78–8. The 12-hour post-dose lithium serum concentration can be 12% to 33% higher with extended-release preparations and lower with regular-release tablets with divided dosage schedules. The dose should be adjusted based on the steady-state serum concentration drawn 12 hours (±30 minutes) after the last dose.[50] A therapeutic trial for outpatients should last a minimum of 4 to 6 weeks with lithium serum concentrations of 0.6 to 1.2 mEq/L (mmol/L). Acutely manic patients can require serum concentrations of 1 to 1.2 mEq/L (mmol/L), and some need up to 1.5 mEq/L (mmol/L) to achieve a therapeutic response. Although serum concentrations less than 0.6 mEq/L (mmol/L) are associated

TABLE 78-8 Guidelines for Baseline and Routine Laboratory Tests and Monitoring for Agents Used in the Treatment of Bipolar Disorder

	Baseline: Physical Examination & General Chemistry[a]	Hematologic Tests[b]		Metabolic Tests[c]		Liver Function Tests[d]		Renal Function Tests[e]		Thyroid Function Tests[f]		Serum Electrolytes[g]		Dermatologic[h]	
	Baseline	*Baseline*	*6–12 mo*	*Baseline*	*6–12 mo*	*Baseline*	*6–12 mo*	*Baseline*	*6–12 mo*	*Baseline*	*6–12 mo*	*Baseline*	*6–12 mo*	*Baseline*	*3–6 mo*
SGAs[i]	X			X	X										
Carbamazepine[j]	X	X	X			X	X	X				X	X	X	X
Lamotrigine[k]	X													X	X
Lithium[l]	X	X	X	X	X			X	X	X	X	X	X	X	X
Oxcarbazepine[m]	X											X	X		
Valproate[n]	X	X	X	X	X	X	X							X	X

[a]Screen for drug abuse and serum pregnancy.
[b]Complete blood cell count (CBC) with differential and platelets.
[c]Fasting glucose, serum lipids, weight.
[d]Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.
[e]Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.
[f]Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.
[g]Serum sodium.
[h]Rashes, hair thinning, alopecia.
[i]Second-generation antipsychotics: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.
[j]Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (e.g., CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are <100,000/mm^3 (<100 × 10^9/L), if white blood cell (WBC) count is <3,000/mm^3 (<3 × 10^9/L) or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.
[k]Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2–8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dosage escalation, or using doses exceeding the recommended titration schedule.
[l]Lithium: Obtain baseline electrocardiogram for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2–3 months during the first 6 months, then every 6–12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume >3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6–12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1–2 months until thyroid function indices are within normal range, then monitor every 3–6 months.
[m]Oxcarbazepine: Hyponatremia (serum sodium concentrations <125 mEq/L [mmol/L]) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (e.g., diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (e.g., confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25%–30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.
[n]Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3–6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are <100,000/mm^3/L (<100 × 10^9/L) or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.
Data from American Psychiatric Association,[2] Goodnick,[10] McEvoy et al.,[49] McEvoy et al.,[54] McEvoy et al.,[58] McEvoy et al.,[60] and McEvoy et al.,[63] and American Diabetes Association et al.[67]

with higher rates of relapse, some patients can do well at 0.4 to 0.7 mEq/L (mmol/L).[2] For bipolar prophylaxis in elderly patients, serum concentrations of 0.4 to 0.6 mEq/L (mmol/L) are recommended because of increased sensitivity to adverse effects.[2]

Anticonvulsants

In the 1980s, anticonvulsants were investigated for manic-depressive illness as the disorder had similar characteristics to episodic neurologic disorders such as epilepsy and migraines. Divalproex sodium (also known as sodium valproate) was marketed in 1995 for the acute treatment of mania in adults and is now the most prescribed mood stabilizer in the United States. Divalproex sodium is FDA approved only for the treatment of acute manic or mixed episodes; however, it is commonly used in clinical practice as maintenance monotherapy for bipolar disorder. Valproate also has limited data supporting its use in acute bipolar depression. Carbamazepine is commonly used for both acute and maintenance therapy. The only formulation approved in the United States for bipolar disorder is extended-release carbamazepine, although other formulations can be used. Some data support the use of oxcarbazepine, a 10-keto analogue of carbamazepine, in the treatment of bipolar disorder; however, it is not approved for the treatment of bipolar disorder in the United States. Valproate, carbamazepine, and oxcarbazepine each have a wide range of neurologic, gastrointestinal, electrolyte, and hematologic adverse effects that requires regular assessment and routine blood work.

Lamotrigine is FDA approved for the maintenance treatment of bipolar I disorder. Lamotrigine add-on or monotherapy has been used for treatment-refractory bipolar depression, but may not be supported by data from numerous clinical trials.[53] Lamotrigine is associated with hypersensitivity reactions and rare life-threatening skin rashes and requires slow dosage titration.[2]

Valproate Sodium and Valproic Acid The exact mechanism of action of valproic acid is not known. Valproic acid is a branched chain fatty acid and was originally used as an organic solvent before it was discovered in the 1960s to have anticonvulsant properties. Valproate has antimigraine, mood-stabilizing, and antiaggressive effects.[54] In 1995, the enteric-coated formulation divalproex sodium (valproate) was approved for the acute treatment of mania. Several controlled studies have shown valproate to be as effective as lithium and olanzapine in patients with pure mania, and it can be more effective than lithium in certain subtypes of bipolar disorder (e.g., rapid cycling, mixed states, bipolar disorder with comorbid substance abuse).[2,3,10,23,55] Placebo- and lithium-controlled and open

studies report that valproate reduces or prevents recurrent manic, depressive, and mixed episodes.[2,3,10] Although valproate is not approved for bipolar disorder in children and adolescents, studies suggest that it is effective and well tolerated.[10,30]

Giving lithium, carbamazepine, antipsychotics, or benzodiazepines with valproate can augment its antimanic effects. The addition of valproate to lithium can have synergistic effects in treatment-refractory rapid cycling and mixed states, and the combination has demonstrated efficacy in maintenance therapy for bipolar I disorder.[23] Combinations of valproate and carbamazepine can have synergistic effects, but the potential drug interactions make blood level monitoring of both agents essential.[10] Adding adjunctive SGAs to valproate can be effective for breakthrough mania or if there is incomplete or partial response to monotherapy. Clozapine, olanzapine, and quetiapine can increase the risk of sedation and weight gain when combined with valproate. The combination of valproate and lamotrigine can be effective, but there is an increased risk of rashes, ataxia, tremor, sedation, and fatigue.[54,56]

Adverse Effects The most frequent dose-related adverse effects with valproate are gastrointestinal complaints (anorexia, nausea, indigestion, vomiting, mild diarrhea, and flatulence), fine hand tremors, and sedation.[2,10,54] The gastrointestinal complaints are usually transient, but giving the medication with food, using lower initial doses with gradual increases in doses, or switching to divalproex sodium extended-release tablets can minimize them.[2,10] Reduction of the dose or the addition of a β-blocker can alleviate tremors, and giving the total daily dose at bedtime can minimize daytime sedation.[2,10]

Other adverse effects of valproate include ataxia, lethargy, alopecia, changes in the texture or color of hair, pruritus, prolonged bleeding because of inhibition of platelet aggregation, transient increases in liver enzymes, and hyperammonemia.[10,54] Increased appetite and weight gain occurs in approximately 50% of patients on long-term valproate therapy. Thrombocytopenia can occur at higher doses, and patients should be monitored for bleeding and bruising. Lowering the valproate dose can restore platelet counts to normal levels.[2] Fatal necrotizing hepatitis is a rare idiosyncratic, non–dose-related adverse effect that has occurred in children with epilepsy receiving multiple anticonvulsants.[10,54] A life-threatening hemorrhagic pancreatitis has been reported in both children and adults.[2,10,54] An in-depth discussion of adverse effects can be found in Chapter 65.

Drug–Drug Interactions A summary of drug–drug interactions for valproate can be found in Chapter 65.

Dosing and Administration For healthy inpatient adults with acute mania, the initial starting dosage of valproate is typically 20 mg/kg/day in divided doses over 12 hours. The daily dose is adjusted by 250 to 500 mg every 1 to 3 days based on clinical response and tolerability. Maximum recommended dosing is 60 mg/kg/day (see Table 78–7).[2,10,54] For outpatients who are hypomanic or euthymic, or for elderly patients, the initial starting dose is generally lower (5–10 mg/kg/day in divided doses) and gradually titrated to avoid adverse effects. Once an optimal dose has been achieved, the total daily dose can be given twice daily or at bedtime if tolerated.[2,10,54] Extended-release divalproex can be administered once daily, but bioavailability can be 15% lower than immediate-release products, thus requiring slightly higher doses.[2] In clinical practice patients with bipolar disorder who are stable can be switched between formulations without having to change the dose. This is not the case for patients with seizure disorder.

Recommended baseline and routine laboratory tests for valproate are listed in Table 78–8. Although therapeutic serum concentrations of valproic acid have not been established in bipolar disorder, most clinicians use the anticonvulsant therapeutic serum range of 50 to 125 mcg/mL (345 to 866 μmol/L) taken 12 hours after the last dose.[2,10] In one study patients with valproate levels greater than 94.1 mcg/mL (651 μmol/L) had greater efficacy for bipolar mania.[57] Patients with cyclothymia or mild bipolar II disorder can have a therapeutic response to lower doses and blood levels, whereas some patients with a more severe form of bipolar disorder can require up to 150 mcg/mL (1,040 μmol/L). Serum valproic acid levels are most useful when assessing for compliance and toxicity.

CLINICAL CONTROVERSY

In the treatment of seizure disorders monitoring serum concentrations of valproic acid is controversial, and the same is true in bipolar disorder. Some clinicians feel that therapeutic blood level monitoring is essential for the appropriate treatment of bipolar disorder, whereas others feel that blood level monitoring is overused and, in many cases, unwarranted. Antiepileptic blood level monitoring should be viewed as a tool to be used as part of overall treatment optimization. Achievement of a specific "therapeutic" level should not be an absolute goal in and of itself.

Carbamazepine Carbamazepine, a dibenzazepine derivative, is structurally related to tricyclic antidepressants.[10] The precise mechanism of action of carbamazepine in affective disorders remains to be elucidated.[12] Carbamazepine is not a first-line agent for bipolar disorder, and is generally reserved for lithium-refractory patients, rapid cyclers, or for mixed states.[2,10] Carbamazepine has acute antimanic effects comparable to lithium and chlorpromazine, but its long-term effectiveness is unclear.[2,10] One comparison trial in hospitalized manic patients indicated that carbamazepine was less effective and needed more rescue adjunctive medications than valproate.[2] Other comparison studies with lithium have reported carbamazepine to be less effective than lithium for maintenance therapy.[2] In a double-blind, placebo-controlled crossover study and in an open study, carbamazepine showed efficacy in the treatment of bipolar depression.[2,10] Studies with treatment-refractory patients have reported that carbamazepine has both acute and long-term prophylactic effects.[3,10] A gradual loss of efficacy over time (similar to lithium and valproate) has been reported in some patients.[3,10]

The combination of carbamazepine with lithium, valproate, and antipsychotics is often used for treatment-resistant patients experiencing a manic episode.[10] Carbamazepine plus olanzapine was not found to be more effective than carbamazepine alone in the treatment of acute mania or mixed episodes.[41] Carbamazepine increases the hepatic metabolism of antidepressants, anticonvulsants, and antipsychotics; thus dosage increases can be necessary (see drug–drug interactions).[10,58] Calcium channel blockers (e.g., verapamil and diltiazem) increase carbamazepine blood levels; thus combination therapy should be closely monitored.[58] The combination of carbamazepine with nimodipine for treatment-refractory bipolar illness can have potential benefit.[59]

Adverse Effects A summary of adverse effects for carbamazepine can be found in Chapter 65. Acute overdoses of carbamazepine are potentially lethal, and serum levels above 15 mcg/mL (63 mmol/L) are associated with ataxia, choreiform movements, diplopia, nystagmus, cardiac conduction changes, seizures, and coma.[2] Gastric lavage, hemoperfusion, and symptomatic treatment are recommended for the management of carbamazepine toxicity.

Drug–Drug Interactions Carbamazepine significantly induces the hepatic cytochrome P450 isoenzyme 3A4 and to a lesser degree 1A2, 2C9/10, and 2D6, which increases the metabolism of many

medications.[2,3,58] Women who receive carbamazepine require higher dosages of oral contraceptives or alternative contraceptive methods.[3]

Carbamazepine is metabolized to an active 10,11-epoxide metabolite, thus medications that inhibit 3A4 isoenzymes can result in carbamazepine toxicity (e.g., cimetidine, diltiazem, erythromycin, fluoxetine, fluvoxamine, isoniazid, itraconazole, ketoconazole, nefazodone, propoxyphene, and verapamil).[2,3,10,58] When carbamazepine is combined with valproate, the carbamazepine dose should be reduced because valproate displaces carbamazepine from protein-binding sites, thus increasing free levels.[3,10] Combining clozapine and carbamazepine is not recommended because of the possibility of bone marrow suppression with both agents.[10]

Dosing and Administration During an acute manic episode in most hospitalized patients, carbamazepine can be started at 400 to 600 mg/day in divided doses with meals and increased by 200 mg/day every 2 to 4 days up to 10 to 15 mg/kg per day. In outpatients the initial dose of carbamazepine should be lower and titrated gradually in order to avoid adverse effects. In clinical practice many patients are able to tolerate once daily dosing of carbamazepine once their mood episode has stabilized. The dose of carbamazepine should be gradually increased until response is achieved or there is evidence of toxicity. During the first month of therapy, serum concentrations of carbamazepine may be effected due to autoinduction of cytochrome P450 3A4 enzymes.[58]

Carbamazepine serum levels are usually obtained every 1 to 2 weeks during the first 2 months, and then every 3 to 6 months during maintenance therapy. Serum levels should be drawn 10 to 12 hours after the dose (trough levels) and at least 4 to 7 days after a dosage change. Although there is no correlation between carbamazepine serum concentration and degree of antimanic or antidepressant response, most clinicians attempt to maintain levels between 6 and 10 mcg/mL (25 and 42 mmol/L) (although some treatment-resistant patients can require serum concentrations of 12–14 mcg/mL [51–59 mmol/L]). Recommended baseline and routine laboratory tests for carbamazepine are listed in Table 78–8.

Oxcarbazepine Oxcarbazepine, a 10-keto analog of carbamazepine, blocks voltage-sensitive sodium channels, modulates voltage-activated calcium currents, and increases potassium conductance.[60] Initial trials suggested oxcarbazepine has mood-stabilizing effects similar to those of carbamazepine, with the advantages of milder adverse effects, no autoinduction of liver enzymes, and potentially fewer drug interactions.[2] There are currently less data supporting the use of oxcarbazepine than carbamazepine in the treatment of bipolar disorder. The APA treatment guidelines recommend the use of oxcarbazepine in any situation where one would use carbamazepine. However, many clinicians prefer to use oxcarbazepine only after a patient has failed treatment with carbamazepine or because of an adverse reaction or side effects. Genuine debate exists regarding drug interactions, side effects, and rates of hyponatremia with oxcarbazepine.

Adverse Effects Oxcarbazepine has dose-related adverse effects of dizziness, sedation, headache, ataxia, fatigue, vertigo, abnormal vision, diplopia, nausea, vomiting, and abdominal pain.[60] In one study, hyponatremia was reported to occur in patients taking oxcarbazepine and carbamazepine at rates of 29.9% and 13.5%, respectively.[61] Severe hyponatremia (sodium less than or equal to 128 mEq/L [mmol/L]) was reported by Dong and coworkers as 12.4% and 2.8% of patients for oxcarbazepine and carbamazepine, respectively.[61] An in-depth discussion of adverse effects can be found in Chapter 65.

Drug–Drug Interactions Oxcarbazepine, a cytochrome P450 2C19 enzyme inhibitor and a 3A3/4 enzyme inducer, has the potential for causing drug interactions.[60] Oxcarbazepine induces the metabolism of oral contraceptives, thus alternative contraceptive measures are required.[3,62]

Dosing and Administration Initial dosing is usually 150 to 300 mg twice daily, and daily doses can be increased by 300 to 600 mg every 3 to 6 days up to 1,200 mg/day in divided doses (with or without food).[60]

Lamotrigine Lamotrigine blocks voltage-sensitive sodium channels, modulates or decreases glutamate and aspartate release, and has antikindling properties.[3,12,53,56,63]

Efficacy The effectiveness of lamotrigine for the maintenance treatment of bipolar I disorder in adult patients was established in two multicenter double-blind, placebo-controlled studies.[2] Doses of 200 mg/day were more effective than lower doses, and there were no advantages to using 400 mg/day. Lamotrigine has both antidepressant and mood-stabilizing effects, it may have augmenting properties when combined with lithium or valproate, and has low rates of switching patients to mania.[56,64] Although lamotrigine is less effective for acute mania compared to standard mood stabilizers, it may be beneficial in the maintenance therapy of treatment-resistant bipolar I and II disorders, in rapid-cycling dysphoric mania, and in mixed states.[2,3,56] Lamotrigine seems to be most effective for the prevention of bipolar depression, therefore clinically it is often used in the treatment of patients with bipolar II. There are case reports of possible lamotrigine induced mania when added to lithium, carbamazepine, and valproate.[65] In each of the cases reported, the patients had depressive mood symptoms or rapid mood changes requiring additional therapy.[65]

Adverse Effects Common adverse effects include headache, nausea, dizziness, ataxia, diplopia, drowsiness, tremor, rash, and pruritus.[56,63] Approximately 10% of patients in premarketing clinical trials developed a maculopapular rash and required discontinuation of therapy.[56,63] Although most rashes are self-limiting and resolve with continued treatment, some cases progressed to life-threatening conditions such as Stevens-Johnson syndrome. The incidence of rash appears to be greatest with coadministration of valproate, with higher than recommended initial doses, and with rapid dose escalation.[63] Patients should be warned about the rash, and the need for discontinuing lamotrigine if the rash is diffuse, involves mucosal membranes, and is accompanied by a fever or sore throat. For an in-depth discussion of the adverse effects of lamotrigine, see Chapter 65.

Drug–Drug Interactions Valproate decreases the clearance of lamotrigine (i.e., more than doubles the half-life), and lamotrigine must be administered at a reduced dosage (approximately half the standard dose).[63] For an in-depth discussion of drug–drug interactions with lamotrigine, see Chapter 65.

Dosing and Administration For the maintenance treatment of bipolar disorder, the usual dosage range of lamotrigine is 50 to 300 mg/day. The target dose is generally 200 mg/day (100 mg/day in combination with valproate and 400 mg/day in combination with carbamazepine).[56,63] For patients not taking medications that affect lamotrigine's clearance, the dose is 25 mg/day for the first 2 weeks of therapy, 50 mg/day for weeks 3 and 4, 100 mg/day for week 5, and 200 mg/day for week 6 and beyond.[2,56,63] Patients who stop lamotrigine therapy for more than a few days should be restarted on the recommended dosage escalation titration schedule.

Antipsychotics

First-generation antipsychotics that block DA_2 receptors and SGAs that block both DA_2 and $5\text{-}HT_{2A}$ receptors are used to decrease DA activity in the treatment of mania and mixed states. First- and second-generation antipsychotics such as aripiprazole, haloperidol, olanzapine, quetiapine, risperidone, and ziprasidone are effective as monotherapy or adjunctive therapy in the treatment of acute mania.[66] Controlled studies in acute mania with lithium or valproate plus an

antipsychotic suggest greater efficacy with combination therapies compared with any of these agents alone.[2,66] First-generation antipsychotics (e.g., chlorpromazine and haloperidol) are effective in up to 70% of patients with acute mania, particularly those with psychosis and psychomotor agitation. Second-generation antipsychotics have demonstrated similar efficacy for the treatment of acute mania associated with agitation, aggression, and psychosis.[2,66]

Treating acute bipolar depression is very challenging, and some antipsychotics may play a useful role. Quetiapine has four large randomized controlled trials supporting its use as a monotherapy treatment option for bipolar depression.[41] The fluoxetine/olanzapine combination also has efficacy data in treating bipolar depression.

Long-term safety of antipsychotics as monotherapy or as an adjunctive therapy for bipolar maintenance treatment still needs to be evaluated.[2,41,66] Risks versus benefits must be weighed due to the long-term adverse effects (e.g., obesity, type 2 diabetes, hyperlipidemia, hyperprolactinemia, and tardive dyskinesia) antipsychotics may cause.[66,68] Aripiprazole, olanzapine, and risperidone long-acting injection are effective monotherapy options for maintenance treatment in bipolar disorder.[41] Some data reported in abstract form support quetiapine for maintenance treatment. First-generation depot antipsychotics (e.g., haloperidol decanoate, fluphenazine decanoate) can have a place in maintenance treatment of bipolar disorder in patients who are noncompliant or treatment resistant.[2]

CLINICAL CONTROVERSY

The use of antipsychotics as long-term maintenance in bipolar disorder does not come without risk. For many years second-generation antipsychotics were considered a safer alternative to first-generation antipsychotics because they had a lower risk for causing movement disorders. However, the second-generation antipsychotics have other long-term risks associated with their use. Metabolic side effects should be considered when weighing risk/benefit ratio of various agents. The optimal management of weight gain and its consequences on physical and mental health is important. Clinicians must make prescribing decisions in collaboration with patients concerning the long-term treatment of bipolar disorder weighing the long-term risk of antipsychotics versus the traditional mood stabilizers (e.g., lithium or valproate).

Clozapine monotherapy has acute and long-term mood-stabilizing effects in refractory bipolar disorder, including conditions with mixed mania and rapid cycling, but requires regular white blood cell monitoring for agranulocytosis.[2,10,66]

Adverse Effects A summary of adverse effects for antipsychotics can be found in Chapter 76.

Drug–Drug Interactions A summary of drug interactions with antipsychotics can be found in Chapter 76.

Dosing and Administration For acute mania, higher initial doses of antipsychotics can be required (e.g., olanzapine 20 mg/day in hospitalized patients). Once acute mania is controlled (usually within 7–28 days), the antipsychotic can be gradually tapered and discontinued, and the patient maintained on the mood stabilizer alone.

Monitoring

6 Recommendations for baseline and routine laboratory testing for patients receiving carbamazepine, lamotrigine, lithium, oxcarbazepine, SGAs, and valproate are found in Table 78–8.

Alternative Medication Treatments

7 **Benzodiazepines** Weighing the risk to benefit ratio, high potency benzodiazepines such as clonazepam and lorazepam are commonly used as an alternative to or in combination with antipsychotics when patients are experiencing acute mania, agitation, anxiety, panic, and insomnia, or cannot take mood stabilizers (e.g., during the first trimester of pregnancy).[2,3,69,70] Lorazepam is available for intramuscular injection and is useful in the acute management of agitation. Benzodiazepines cause minimal adverse effects compared with antipsychotics, and at higher doses, rapidly sedate agitated patients.[3] Benzodiazepines can cause central nervous system depression, sedation, cognitive and motor impairment, dependence, and withdrawal reactions. When no longer required, benzodiazepines should be gradually tapered and discontinued to avoid withdrawal symptoms.

Antidepressants For many years antidepressants were recommended as adjunctive therapy for acute bipolar depression. Recent data from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) suggest that adjunctive antidepressants may be no better than placebo for acute bipolar depression when combined with mood stabilizers.[71] Controversy exists concerning the use of antidepressants, and many clinicians consider them third line in treating acute bipolar depression, except in patients with no history of severe and/or recent mania or potentially in bipolar II patients.[72] The concern of mood switching with the use of antidepressants is valid, although not common. Data show that the rates of mood switch with SSRIs is around 3.8%, similar to placebo when combined with mood stabilizers. The rate of mood switch with dual acting agents (e.g., TCAs or venlafaxine) is higher, and thus these agents should be used with caution.[72,73] It is very important that before initiating therapy with an antidepressant, the patient should be on a therapeutic dosage or blood level of a primary mood stabilizer.[2] Patients who have a history of mania after a depressive episode or who have frequent cycling should be treated cautiously with antidepressants.[2,3] In general, the antidepressant should be gradually withdrawn 2 to 6 months after remission, and the patient maintained on a mood-stabilizing agent.[28,74] For more information, see Chapter 77 for comparisons among antidepressants.

CLINICAL CONTROVERSY

The use of antidepressants in treating bipolar depression does not appear to have benefit over placebo according to recently published data from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD). There are however meta-analysis data that show some utility of antidepressants. Antidepressants are no longer considered first line in treating bipolar depression, unless a patient has no recent or severe history of acute mania.

Calcium Channel Antagonists Calcium channel antagonists inactivate voltage-sensitive calcium channels, thus inhibiting neurotransmitter synthesis and release and neuronal signal transmission.[10,12] Verapamil, a nondihydropyridine, has demonstrated mood-stabilizing properties in some studies, but negative results were found in other trials.[2,3,10,75] Nimodipine, a dihydropyridine, can be more effective than verapamil for rapid-cycling bipolar disorder because of its anticonvulsant properties, high lipid solubility, and good penetration into the brain.[2,3,10,12,31,75] Calcium channel blockers are generally well tolerated, and the most common adverse effects are bradycardia and hypotension. These are seldom used in everyday clinical practice.

Newer Anticonvulsants Third-generation anticonvulsants have been investigated for treating bipolar disorder with the hope that a different mechanism of action would be beneficial for mood stabilization. Gabapentin, levetiracetam, tiagabine, topiramate, and zonasimide have negative or limited positive data supporting their use in bipolar disorder. Topiramate has been used as an add-on weight-reduction medication, but there are no randomized controlled trials supporting its use in bipolar disorder.[76]

Novel Agents and Dietary Intake Disturbances in 5-HT neurotransmission secondary to inadequate dietary L-tryptophan or abnormalities in tryptophan hydroxylase, 5-HT transporters, and 5-HT receptors was implicated in the pathophysiology of manic-depressive illness as early as 1958.[10] Low 5-HT activity may be a trait marker for bipolar disorder.[21] If available 5-HT is low, the synthesis and secretion of melatonin can be disrupted, thus causing circadian rhythm changes.[10] Acute tryptophan depletion has been shown to reverse the antidepressant effects of 5-HT reuptake inhibitors in depressed patients in remission, but may not negatively affect mood in lithium-stabilized bipolar patients.[77] Randomized controlled studies of L-tryptophan or 5-hydroxytryptophan have shown positive results in the acute treatment and prophylaxis of bipolar disorder.[10] Because 5-HT synthesis in the brain is dependent on dietary L-tryptophan intake, the importance of adequate and regular ingestion of animal-derived protein should be discussed with patients.[10]

A dietary deficiency in essential fatty acids (found in certain fish oils and flaxseed oil that contains α-linolenic acid) has been proposed as a potential cause of mood disorders.[78,79] Omega-3 fatty acids have been shown to suppress neuronal pathways and inhibit kindling processes by several mechanisms (e.g., inhibition of phosphatidylinositol and G-protein secondary messengers and blocking L-type calcium channels). Seafood and fish are rich dietary sources of omega-3 essential fatty acids, specifically docosahexaenoic acid and eicosapentaenoic acid.[79] Omega-3 fatty acids may have more antidepressant than antimanic effects.[80] Data reported by Keck and colleagues for bipolar depression and rapid cycling did not support the use of eicosapentaenoic acid.[81] The data supporting the use of omega-3 fatty acids is controversial and needs to be further evaluated.

Special Populations

The approach for treating bipolar disorder in special populations (e.g., comorbid medical or psychiatric disorders, pregnancy, or breastfeeding) can vary among clinicians. Patients with comorbid medical conditions or concomitant substance abuse, those older than 65 years of age, and pregnant patients can require different treatment approaches. Women have a high risk of relapse postpartum; therefore, prophylaxis with mood stabilizers is recommended immediately postpartum to decrease the risk of relapse.[82]

Prophylactic medications such as lithium or valproate can prevent postpartum episodes in women with bipolar disorder.[2] Pharmacotherapy during pregnancy is complicated, and the risk-to-benefit ratio must be weighed. Infants whose mothers took lithium during the first trimester of pregnancy may have a lower incidence of cardiovascular defects (particularly Ebstein anomaly) than was previously thought.[2,10] Current estimates of this malformation during the first trimester are estimated between 1:1,000 and 1:2,000.[82] Lithium freely crosses the placenta and is found in equal concentrations in maternal and fetal blood.[49] When lithium is used during pregnancy, it should be tapered down to the lowest effective dose necessary to decrease the risk of relapse. Lithium can cause "floppy" infant syndrome (e.g., low Apgar scores, lethargy, hypotonia, bradycardia, cyanosis, shallow respiration, and poor sucking), hypothyroidism, and nontoxic goiters. Milk concentrations of lithium range from 30% to 50% of the mother's serum concentration, and serum concentrations in the nursing infant are 10% to 50% of the mother's; thus breastfeeding is usually discouraged.[2,11,83] If using lithium during pregnancy, dose adjustments and close monitoring of serum levels will be needed due to changes in glomerular filtration rates and renal perfusion rates during pregnancy and immediately after delivery.[84]

The use of anticonvulsants also poses a teratogenic risk when used during pregnancy. Neural tube defects cause the most concern for clinicians treating pregnant patients during their first trimester of pregnancy. Data from the North American Antiepileptic Drug Pregnancy Registry shows the risk of neural tube defects is about 1 in 1,500 for nonexposed babies.[85] Carbamazepine's risk of neural tube defects is estimated to be 0.5% to 1%.[12] Carbamazepine is excreted in breast milk (the milk-to-maternal plasma ratio of carbamazepine is ~0.4).[3] Craniofacial abnormalities, developmental delays, microcephaly, and other abnormalities are also of concern when using anticonvulsants. Data on lamotrigine show major malformation rates similar to the general population (2.9% vs 2%–3%, respectively), but data for lamotrigine is limited compared with some older anticonvulsants.[84] The International Lamotrigine Pregnancy Register reports 12 major congenital malformations from 414 first trimester exposures.[84] Valproate is usually not recommended during the first trimester of pregnancy because the risk of neural tube birth defects is about 1 in 20 exposed babies.[85] Australian registry data in patients with epilepsy show dose-related teratogenicity with doses greater than 1,100 mg/day of valproate.[86] Administration of folate can reduce the risk of neural tube defects; therefore the risks versus benefits of using valproate during pregnancy must be discussed with the patient.[10] Valproic acid is excreted into human breast milk in low concentrations (less than 1%–10% of the mother's serum level), so is considered to be compatible with breastfeeding.[3] One case report of thrombocytopenia and anemia from valproate exposure has been reported in a nursing infant. If the mother receives valproate during breastfeeding, mother and infant should have identical laboratory monitoring. Caution should be used when prescribing antipsychotics during pregnancy. There are far more data on the use of FGAs than SGAs during pregnancy. Some data are available for haloperidol and low-dose chlorpromazine, and these data show no elevated rate of physical malformations during first trimester exposure.[87] Higher doses of chlorpromazine used in treating psychiatric illness may be associated with neonatal withdrawal and extrapyramidal symptoms.[87] Data on other FGAs are limited. Data on the SGAs are more limited, but do not show an overall increased risk of fetal abnormalities.[87] Olanzapine, risperidone, and quetiapine comprise most of this data.[87] There are limited reports with clozapine, aripiprazole, and ziprasidone.[87] There is still a paucity of human data with antipsychotics and therefore risk-benefit ratio must be weighed.

Treatment of catatonia also varies from standard treatment in that mood stabilizers and antipsychotics have minimal effect. Catatonic features such as mutism, motor excitement, stereotypic movements, waxy flexibility, negativism, echopraxia, and echolalia are best treated with benzodiazepines, specifically lorazepam. The use of antipsychotics in catatonia should be minimized because of an increased risk of neuroleptic malignant syndrome. ECT is also a treatment option in this patient population.

PHARMACOECONOMIC CONSIDERATIONS

Bipolar disorder is one of the leading causes of chronic disability worldwide and shares characteristics of both major depressive disorder and schizophrenia.[3] Bipolar disorder is primarily treated in the public mental health sector, and a majority of patients receive lifelong disability coverage because of compromised functioning.[3]

The total cost to society for bipolar disorder is enormous and is exceeded only by the costs for treating individuals with schizophrenia.[10] It was estimated, more than a decade ago, that the total annual economic impact of bipolar disorder in the United States was approximately $45 billion per year.[88]

EVALUATION OF THERAPEUTIC OUTCOMES

The establishment and maintenance of a therapeutic alliance with a clinician is essential in monitoring a patient's psychiatric status and safety; enhancing treatment adherence; promoting good nutrition, sleep, and exercise; identifying stressors; recognizing new mood episodes; and minimizing adverse reactions and drug interactions.[2] Patients who have a partial response or nonresponse to established bipolar therapies should be reassessed for an accurate diagnosis, concomitant medical or psychiatric conditions, and medications or substances that exacerbate mood symptoms. Nonadherence to medication treatment, delusional symptoms, alcohol or substance abuse, rapid cycling, or mixed states are often associated with poorer treatment outcomes.

The evaluation of therapeutic outcomes for bipolar disorder requires regular monitoring by a clinician. More frequent office visits, telephone calls, and intensive outpatient programs are first-line strategies to prevent hospitalization during the acute treatment phase of a manic or depressive episode.[2] Patients (and family members if needed) should be actively involved with their treatment and help to monitor target symptoms, efficacy of treatment, treatment adherence, and adverse effects.[2]

Standardized rating scales for mania and depression are used to measure severity and changes in symptoms in clinical trials (e.g., Young Mania Rating Scale, brief bipolar disorder symptoms scale, Hamilton Rating Scale for Depression, and Montgomery-Åsberg Depression Rating Scale). Patient-rated life mood charts, a timeline of stressful life events, and a graphic display of sleep patterns are helpful in recognizing early symptoms of mood episodes and in documenting patterns and lengths of episodes.[2] A mood disorder questionnaire, a 13-item self-reported screening tool, was developed to differentiate bipolar disorder from other mood disorders (*www.dbsalliance.org/questionnaire/screening_intro.asp*).[2,25] Health-related quality of life scales such as the Short Form (SF)-36 and the Psychological General Well-Being Scale have been recommended to assess the quality of life in individuals with bipolar disorder.[89]

CHAPTER 79

Anxiety Disorders I: Generalized Anxiety, Panic, and Social Anxiety Disorders

SARAH T. MELTON AND CYNTHIA K. KIRKWOOD

KEY CONCEPTS

1. The long-term goal in generalized anxiety disorder (GAD) is remission with minimal or no anxiety symptoms and no functional impairment.
2. Antidepressants are the agents of choice for the management of GAD.
3. Antidepressants have a lag time of 2 to 4 weeks or longer before antianxiety effects occur in GAD.
4. When monitoring the effectiveness of antidepressants in panic disorder, it is important to allow an adequate amount of time (8 to 12 weeks) to achieve full therapeutic response.
5. Clonazepam and extended-release alprazolam are alternatives to immediate-release alprazolam for patients with panic disorder having breakthrough panic symptoms at the end of a dosing interval.
6. The optimal duration of panic therapy is unknown; 12 to 24 months of pharmacotherapy is recommended before gradual drug discontinuation over 4 to 6 months is attempted.
7. Social anxiety disorder (SAD) is a chronic long-term illness requiring extended therapy. After improvement, at least a 1-year medication maintenance period is recommended.
8. The selective serotonin reuptake inhibitors or venlafaxine are considered first-line pharmacotherapy for SAD.
9. An adequate trial of antidepressants in generalized social anxiety disorder lasts at least 8 weeks, and maximal benefit may not be seen until 12 weeks.
10. The three principal domains in which improvement should be observed in generalized social anxiety disorder are symptoms, functionality, and well-being.

Anxiety is an emotional state commonly caused by the perception of real or perceived danger that threatens the security of an individual. It allows a person to prepare for or react to environmental changes. Everyone experiences a certain amount of nervousness and apprehension when faced with a stressful situation. This is an adaptive response and is transient in nature.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Anxiety can produce uncomfortable and potentially debilitating psychologic (e.g., worry or feeling of threat) and physiologic arousal (e.g., tachycardia or shortness of breath) if it becomes excessive. Some individuals experience persistent, severe anxiety symptoms and possess irrational fears that significantly impair normal daily functioning. These persons often suffer from an anxiety disorder.[1]

Anxiety disorders are among the most frequent mental disorders encountered in clinical practice. Healthcare professionals often mistake anxiety disorders for physical illnesses, and only 23% of patients receive appropriate treatment.[2] Failure to diagnose and manage anxiety disorders results in negative outcomes including overuse of healthcare resources, increased morbidity, and mortality.[3] Individuals with anxiety disorders develop cardiovascular, cerebrovascular, gastrointestinal, and respiratory disorders at a significantly higher rate than the general population.[4]

To treat anxiety appropriately, the clinician must make a reliable diagnosis. It is essential that the distinction between short-term symptoms of anxiety and anxiety disorders be understood. Common or situational anxiety is a normal response to a stressful circumstance. Although symptoms can be severe, they are temporary and usually last no more than 2 or 3 weeks. Although short-term, as-needed treatment with an anxiolytic agent such as a benzodiazepine is common and can provide some symptomatic relief, prolonged drug therapy is not recommended.[5]

EPIDEMIOLOGY

Anxiety disorders, as a group, are the most commonly occurring psychiatric disorders. According to the National Comorbidity Survey Replication on the prevalence, severity, and comorbidity estimates of mental disorders in the United States, the most recent 1-year prevalence rate for anxiety disorders was 19.1% in persons aged 18 years and older. Specific phobias were the most common anxiety disorder, with a 12-month prevalence of 9.1%. The 1-year prevalence of generalized anxiety disorder (GAD) was 2.7%, that of panic disorder was 2.7%, and that of social anxiety disorder (SAD) was 7.1%.[6]

In general, anxiety disorders are a group of heterogeneous illnesses that develop before age 30 years and are more common in women, individuals with social issues, and those with a family history of anxiety and depression. Patients often develop another anxiety disorder, major depression, or substance abuse.[1–3] The clinical picture of mixed anxiety and depression is much more common than an isolated anxiety disorder.[2]

ETIOLOGY

The differential diagnosis of anxiety disorders includes medical and psychiatric illnesses and certain drugs.[2] Hypotheses on the etiology of anxiety disorders are based on interactions between a combination of

TABLE 79-1 Common Medical Illnesses Associated with Anxiety Symptoms

Cardiovascular	
Angina, arrhythmias, cardiomyopathy, congestive heart failure, hypertension, ischemic heart disease, myocardial infarction	
Endocrine and metabolic	
Cushing's disease, diabetes, hyperparathyroidism, hyperthyroidism, hypothyroidism, hypoglycemia, hyponatremia, hyperkalemia, pheochromocytoma, vitamin B_{12} or folate deficiencies	
Neurologic	
Migraine, seizures, stroke, neoplasms, poor pain control	
Respiratory system	
Asthma, chronic obstructive pulmonary disease, pulmonary embolism, pneumonia	
Others	
Anemias, cancer, systemic lupus erythematosus, vestibular dysfunction	

Data from Roy-Byrne et al.[2,4] and Rogers and Wolfe.[10]

factors including vulnerability (e.g., genetic predisposition and early childhood adversity) and stress (e.g., occupational and traumatic experience). The vulnerability may be associated with genetic factors and neurobiological adaptations of the central nervous system (CNS).[7]

MEDICAL DISEASES ASSOCIATED WITH ANXIETY

Anxiety symptoms are an inherent part of the initial clinical presentation of several diseases, thus complicating the distinction between anxiety disorders and medical disorders.[2,4] Anxiety disorders are strongly and independently associated with chronic medical illness, low levels of physical health-related quality of life (QOL), and physical disability.[4] If anxiety symptoms are secondary to a medical illness, they usually will subside as the medical situation stabilizes. However, the knowledge that one has a physical illness can trigger anxious feelings and further complicate therapy. Persistent anxiety subsequent to a physical illness requires further assessment for an anxiety disorder. Common somatic symptoms of anxiety that frequently present in medical disorders include abdominal pain, palpitations, tachycardia, sweating, flushing, tremor, chest pain or tightness, and shortness of breath. Although less specific, symptoms of muscle tension, headache, and fatigue are also common manifestations of anxiety. Medical disorders most closely associated with anxiety are listed in Table 79–1.[2,4,8–10]

PSYCHIATRIC DISEASES ASSOCIATED WITH ANXIETY

Anxiety can be a presenting feature of several major psychiatric illnesses. Anxiety symptoms are extremely common in patients with mood disorders, schizophrenia, dementia, and substance use disorders. Most psychiatric patients will have two or more concurrent psychiatric disorders (comorbidity) within their lifetime.[6] It is important to diagnose and treat all comorbid psychiatric conditions in patients with anxiety disorders.

DRUG-INDUCED ANXIETY

Drugs are a common cause of anxiety symptoms (Table 79–2). Anxiety occurs during the use of CNS-stimulating drugs in a dose-dependent manner, but ingestion of minimal amounts can result in marked anxiety, including panic attacks, in some individuals. The onset of drug-induced anxiety is usually rapid after the initiation of therapy. A thorough medication history evaluating for a recent drug or dosage change is important to rule out a drug-induced etiology for the anxiety.

TABLE 79-2 Drugs Associated with Anxiety Symptoms

Anticonvulsants: carbamazepine, phenytoin
Antidepressants: selective serotonin reuptake inhibitors, serotonin norepinephrine reuptake inhibitors, bupropion
Antihypertensives: clonidine, felodipine
Antibiotics: quinolones, isoniazid
Bronchodilators: albuterol, theophylline
Corticosteroids: prednisone
Dopa agonists: amantadine, levodopa
Herbals: ma huang, ginseng, ephedra
Illicit substances: ecstasy, marijuana
Nonsteroidal antiinflammatory drugs: ibuprofen, indomethacin
Stimulants: amphetamines, methylphenidate, nicotine, caffeine, cocaine
Sympathomimetics: pseudoephedrine, phenylephrine
Thyroid hormones: levothyroxine
Toxicity: anticholinergics, antihistamines, digoxin

Data from American Psychiatric Association[1] and Rogers and Wolfe.[10]

Anxiety occurs occasionally during the use of CNS depressants, especially in children and the elderly; however, anxiety complaints are more common as complications of drug withdrawal after the abrupt discontinuation of these agents.[8–10]

PATHOPHYSIOLOGY

Data from biochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain and abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ-aminobutyric acid (GABA), serotonin (5-HT), corticotrophin-releasing factor (CRF), and cholesystokinin.[11] Current neuroanatomic models of fear (i.e., the response to danger) and anxiety (i.e., the feeling of fear that is disproportionate to the actual threat) include some key brain areas. The amygdala, a temporal lobe structure, plays a critical role in the assessment of fear stimuli and learned response to fear.[11,12] The locus ceruleus (LC), located in the brain stem, is the primary NE-containing site, with widespread projections to areas responsible for implementing fear responses (e.g., vagus, lateral and paraventricular hypothalamus). The hippocampus is integral in the consolidation of traumatic memory and contextual fear conditioning. The hypothalamus is the principal area for integrating neuroendocrine and autonomic responses to a threat.[11,12]

NEUROCHEMICAL THEORIES

Noradrenergic Model

The basic premise of the noradrenergic theory is that the autonomic nervous system of anxious patients is hypersensitive and overreacts to various stimuli. Many anxious patients clearly display symptoms of peripheral autonomic hyperactivity. In response to threat or fearful situations, the LC serves as an alarm center, activating NE release and stimulating the sympathetic and parasympathetic nervous systems. Chronic central noradrenergic overactivity downregulates α_2-adrenoreceptors in patients with GAD. This receptor is hypersensitive in some patients with panic disorder.[11] By administering drugs that have a relatively specific effect on the LC, researchers have further explored the NE theory of anxiety and panic disorder. Drugs with anxiogenic effects (e.g., yohimbine [an α_2-adrenergic receptor antagonist]) stimulate LC firing and increase noradrenergic activity. NE in turn increases glutamate release (an excitatory neurotransmitter).[11] This produces subjective feelings of anxiety and can precipitate a panic attack in those with panic disorder, but not in normal volunteers.[11] Drugs with anxiolytic or antipanic effects

(e.g., benzodiazepines and antidepressants) inhibit LC firing, decrease noradrenergic activity, and block the effects of anxiogenic drugs.[11]

GABA Receptor Model

There are two superfamilies of GABA protein receptors: $GABA_A$ and $GABA_B$. Drugs that reduce anxiety and produce sedation target the $GABA_A$ receptor. The $GABA_B$ receptor is a G-protein coupled receptor postulated to be involved in the presynaptic inhibition of GABA release.[11–13] $GABA_A$ receptors are ligand-gated ion channels composed of five protein subunits. Several classes of subunits (i.e., $\alpha_{1-6}, \beta_{1-3}, \gamma_{1-3}, \delta, \varepsilon, \theta, \pi, \rho, _{1-3}$) surround a central pore, and the receptor is connected to the cytoskeleton.[14] Benzodiazepine ligands enhance the inhibitory effects of GABA.[11,13] GABA, the major inhibitory neurotransmitter in the CNS, has a strong regulatory or inhibitory effect on the 5-HT, NE, and dopamine (DA) systems. When GABA binds to the $GABA_A$ receptor, neuronal excitability is reduced.

The specific role of the GABA receptors in anxiety disorders has not been established. The number of $GABA_A$ receptors can change with alterations in the environment (e.g., chronic stress), and the subunit expression can be altered by hormonal changes.[14] In patients with GAD, benzodiazepine binding in the left temporal lobe is reduced.[14] Abnormal sensitivity to antagonism of the benzodiazepine binding site and decreased binding was demonstrated in panic disorder.[11,14] This is consistent with the suggestion that panic disorder is secondary to a lack of central inhibition that results in uncontrolled elevations in anxiety during panic attacks.[13] Growth hormone response to baclofen in patients with generalized SAD suggests an abnormality of central $GABA_B$ receptor function.[15]

Serotonin Model

Although there are data suggesting that the 5-HT system is dysregulated in patients with anxiety disorders, definitive evidence that shows a clear abnormality in 5-HT function is lacking. 5-HT is primarily an inhibitory neurotransmitter that is used by neurons originating in the raphe nuclei of the brain stem and projecting diffusely throughout the brain (e.g., cortex, amygdala, hippocampus, and limbic system). Abnormalities in serotonergic functioning through release and uptake at the presynaptic autoreceptors ($5\text{-}HT_{1A/1D}$), the serotonin reuptake transporter (SERT) site, or effect of 5-HT at the postsynaptic receptors (e.g., $5\text{-}HT_{1A}$, $5\text{-}HT_{2A}$, and $5\text{-}HT_{2C}$) may play a role in anxiety disorders.[11,13] Preclinical models suggest that greater 5-HT function facilitates avoidance behavior; however, primate studies show that reducing 5-HT increases aggression.[11,13] It is postulated that greater 5-HT activity reduces NE activity in the LC, inhibits defense/escape response via the periaqueductal gray (PAG) region, and reduces hypothalamic release of CRF. The selective serotonin reuptake inhibitors (SSRIs) acutely increase 5-HT levels by blocking the SERT to increase the amount of 5-HT available postsynaptically, and are efficacious in blocking the manifestations of panic and anxiety.[11]

Low 5-HT activity may lead to a dysregulation of other neurotransmitters. NE and 5-HT systems are closely linked, and interactions between the two are reciprocal and vary. NE may act at presynaptic 5-HT terminals to decrease 5-HT release, and its activity at postsynaptic receptors can cause increased 5-HT release.

Buspirone is a selective $5\text{-}HT_{1A}$ partial agonist that is effective for GAD but not for panic disorder. Because the selective $5\text{-}HT_{1A}$ partial agonists reduce serotonergic activity, GAD symptoms may reflect excessive 5-HT transmission or overactivity of the stimulatory 5-HT pathways.[16] The comparable efficacy of the serotonin-norepinephrine reuptake inhibitor (SNRI), extended-release venlafaxine, at high and low dosages suggests that 5-HT (rather than NE) reuptake blockade contributes to the therapeutic effect in SAD.[17]

NEUROIMAGING STUDIES

Functional neuroimaging studies support the crucial role of the amygdala, anterior cingulate cortex (ACC) and insula in the pathophysiology of anxiety.[12] In GAD there is an abnormal increase in the brain's fear circuitry, as well as increased activity in the prefrontal cortex, which appears to have a compensatory role in reducing GAD symptoms.[18] Patients with panic have abnormalities of midbrain structures, including the PAG. Neuroimaging studies have shown activation of insula and upper brain stem (including the PAG), as well as deactivation of the ACC during experimental panic attacks.[19] Patients with SAD have greater activity than matched comparison subjects in the amygdala and insula, structures linked to negative emotional responses.[20] Both pharmacotherapy and psychotherapy decreased cerebral blood flow in the amygdala, hippocampus, and surrounding cortical areas in patients with SAD.[17]

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* classifies anxiety disorders into several categories: GAD, panic disorder (with or without agoraphobia), agoraphobia, SAD, specific phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and acute stress disorder.[1] The characteristic features of these illnesses are anxiety and avoidance behavior. Anxiety symptoms must cause significant distress, and impairment in social, occupational, or other areas of functioning and should not be secondary to a drug or illicit substance or a general medical disorder, or occur solely as part of another psychiatric disorder.[1] OCD and PTSD are discussed in Chapter 80.

GENERALIZED ANXIETY DISORDER

The diagnostic criteria for GAD require persistent symptoms for most days for at least 6 months.[1] The essential feature of GAD is unrealistic or excessive anxiety and worry about a number of events or activities.[1] The anxiety or apprehensive expectation is accompanied by at least three psychologic or physiologic symptoms. Anxiety and worry are not confined to features of another psychiatric illness (e.g., having a panic attack, being embarrassed in public).[1]

CLINICAL PRESENTATION OF GENERALIZED ANXIETY DISORDER

Psychologic and Cognitive Symptoms

- Excessive anxiety
- Worries that are difficult to control
- Feeling keyed up or on edge
- Poor concentration or mind going blank

Physical Symptoms

- Restlessness
- Fatigue
- Muscle tension
- Sleep disturbance
- Irritability

Impairment

- Social, occupational, or other important functional areas
- Poor coping skills

Data from American Psychiatric Association[1] and Baldwin et al.[21]

The onset, course of illness, and comorbid conditions of GAD are important considerations. GAD has a gradual onset with an average age of 21 years; however, there is a bimodal distribution. Onset occurs earlier when GAD is the primary presentation and later when GAD is secondary. GAD can be exacerbated or precipitated in later life by severe psychologic stressors. Most patients present between the ages of 35 and 45 years, with women twice as likely to have GAD as men. GAD is the most common anxiety disorder in patients older than 55 years of age.[9] Tension surrounding life events also can play a role in the persistence of symptoms. The course of the illness is chronic (i.e., episodes can last for a decade or longer); there is a high percentage of relapse and low rates of recovery. The likelihood of remission at 2 years is 25%.[1] Patients report substantial interference with their lives and have a high probability of seeking treatment.[8] Lifetime comorbidity with another psychiatric disorder occurs in 90% of patients with GAD, with depression being found in over 60%.[8]

PANIC DISORDER

Panic disorder begins as a series of unexpected (spontaneous) panic attacks involving an intense, terrifying fear similar to that caused by life-threatening danger. The unexpected panic attacks are followed by at least 1 month of persistent concern about having another panic attack, worry about the possible consequences of the panic attack, or a significant behavioral change related to the attacks.[1] During an attack, patients describe at least four physiologic and physical symptoms. Panic attacks usually last no more than 20 to 30 minutes, with the peak intensity of symptoms within the first 10 minutes. Often patients seek help at a physician's office or emergency department, only to have their symptoms resolve before or on arrival. Because panic symptoms mimic those present in several medical conditions, patients often are misdiagnosed, and multiple referrals are common.[1]

CLINICAL PRESENTATION OF A PANIC ATTACK

Psychological Symptoms

- Depersonalization
- Derealization
- Fear of losing control, going crazy, or dying

Physical Symptoms

- Abdominal distress
- Chest pain or discomfort
- Chills
- Dizziness or light-headedness
- Feeling of choking
- Hot flushes
- Palpitations
- Nausea
- Paresthesias
- Shortness of breath
- Sweating
- Tachycardia
- Trembling or shaking

Data from American Psychiatric Association,[1] Baldwin et al.,[21] and Katon.[22]

Secondary to the panic attacks, up to 70% of patients develop agoraphobia.[22,23] Agoraphobia is anxiety about being in places or situations in which escape might be difficult or where help might not be available in the event of a panic attack.[1] As a result, patients often avoid specific situations (e.g., being in a crowd or flying) in which they fear a panic attack might occur.[1]

Complications of panic disorder include depression (10%–65% have major depressive disorder), alcohol abuse, and high use of health services and emergency rooms.[1] Patients with panic disorder have a high lifetime risk for suicide attempts compared with the general population.[22,23] The usual course is chronic but waxing and waning.

SOCIAL ANXIETY DISORDER

SAD is characterized by an intense, irrational, and persistent fear of being negatively evaluated or scrutinized in at least one social or performance situation. Exposure to the feared circumstance usually provokes an immediate situation-related panic attack. Blushing is the principal physical indicator and distinguishes SAD from other anxiety disorders. Adults with SAD usually recognize their fear is excessive and unreasonable; however, they are unable to overcome it without treatment. If necessary, the feared situation is avoided or endured with significant distress.[1] In individuals younger than 18 years of age, the duration of symptoms must be at least 6 months to meet the diagnostic criteria.[1]

CLINICAL PRESENTATION OF SOCIAL ANXIETY DISORDER

Fears of Being

- Scrutinized by others
- Embarrassed
- Humiliated

Some Feared Situations

- Eating or writing in front of others
- Interacting with authority figures
- Speaking in public
- Talking with strangers
- Use of public toilets

Physical Symptoms

- Blushing
- "Butterflies in the stomach"
- Diarrhea
- Sweating
- Tachycardia
- Trembling

Types

- Generalized: fear and avoidance extend to a wide range of social situations
- Nongeneralized: fear limited to one or two situations

Data from American Psychiatric Association,[1] Muller et al.,[17] and Schneier.[24]

The mean age of onset of SAD is during the mid-teens. Rates of SAD are slightly higher among women than men and more frequent in younger cohorts. It is a chronic disorder with a mean duration of 20 years.[1] People with SAD can be reluctant to seek professional help, despite the existence of beneficial treatments because consultation with a clinician is perceived as a feared social interaction.[17,24]

Differentiating SAD from other anxiety disorders can be difficult. Panic attacks occur in both SAD and panic disorder, but

the distinction between the two is the rationale behind fear; fear of anxiety symptoms is characteristic of panic disorder, whereas fear of embarrassment from social interaction typifies SAD.[1] A majority of SAD patients eventually develop a concurrent mood, anxiety, or substance abuse disorder.[17,23]

SPECIFIC PHOBIA

Specific phobia is marked and persistent fear of a circumscribed object or situation (e.g., insects, or heights). Apart from contact with the feared object or situation, the patient is usually free of symptoms. Most persons simply avoid the feared object and adjust to certain restrictions on their activities.[1]

TREATMENT

Generalized Anxiety Disorder

DESIRED OUTCOME

The goals of therapy in the acute management of GAD are to reduce the severity and duration of the anxiety symptoms and to improve overall functioning. 1 The long-term goal in GAD is remission with minimal or no anxiety symptoms, no functional impairment, and increased QOL.[25] Prevention of recurrence is another long-term consideration.

GENERAL APPROACH TO TREATMENT

Once GAD is diagnosed, a patient-oriented treatment plan, which usually consists of both psychotherapy and drug therapy, is developed. The plan depends on the severity and chronicity of symptoms, age, medication history, and comorbid medical and psychiatric conditions.[9,25] Factors such as anticipated adverse effects, history of prior response in the patient or family member, patient preference, and cost should be considered when treatment is initiated. Psychotherapy is the least invasive and safest treatment modality. Antianxiety medication is indicated for patients experiencing symptoms severe enough to produce functional disability. Table 79–3 lists drug choices for GAD, panic disorder, and SAD.

TABLE 79-3 Drug Choices for Anxiety Disorders

Anxiety Disorder	First Line Drugs	Second Line Drugs	Alternatives
Generalized anxiety	Duloxetine Escitalopram Paroxetine Sertraline Venlafaxine XR	Benzodiazepines Buspirone Imipramine	Hydroxyzine Pregabalin Quetiapine
Panic disorder	SSRIs Venlafaxine XR	Alprazolam Citalopram Clomipramine Clonazepam Imipramine	Phenelzine
Social anxiety disorder	Escitalopram Fluvoxamine CR Paroxetine Sertraline Venlafaxine XR	Clonazepam Citalopram	Clonazepam Gabapentin Mirtazapine Phenelzine Pregabalin

SSRI, selective serotonin reuptake inhibitor; XR, extended-release; CR, controlled-release.
Data from Bandelow et al.,[3] Davidson et al.,[8] Baldwin et al.,[21] Schneier,[24] and American Psychiatric Association.[26]

NONPHARMACOLOGIC THERAPY

Nonpharmacologic treatment modalities in GAD include psychoeducation, short-term counseling, stress management, psychotherapy, meditation, or exercise. Psychoeducation includes information on the etiology and management of GAD. Anxious patients should be instructed to avoid caffeine, nonprescription stimulants, diet pills, and excessive use of alcohol. Most patients with GAD require psychologic therapy, alone or in combination with antianxiety drugs, to overcome fears and to learn to manage their anxiety and worry.[5] Cognitive behavioral therapy (CBT) is the most effective psychologic therapy in GAD patients. CBT for GAD includes self-monitoring of worry, cognitive restructuring, relaxation training, and rehearsal of coping skills.[5] Psychotherapy or medication alone have comparable efficacy in acute treatment.[21] The relapse rate with CBT is less than with other types of psychologic modalities.[21] Controlled trials comparing the efficacy of combining drug and psychotherapy over long-term treatment are lacking.[21] Advantages of CBT over pharmacotherapy include patient preference and lack of troubling adverse effects. However, CBT is not widely available, requires specialized training, and entails weekly sessions for an extended time period (i.e., 12–20 weeks).[5]

PHARMACOLOGIC THERAPY

The benzodiazepines are the most effective, safe, and commonly prescribed drugs for the rapid relief of acute anxiety symptoms (Table 79–4). All benzodiazepines are equally effective anxiolytics, and consideration of pharmacokinetic properties and the patient's clinical situation will assist in the selection of the most appropriate agent.[5]

Because of the lack of dependency and tolerable adverse effect profile, antidepressants have emerged as the treatment of choice for the management of chronic anxiety, especially in the presence of comorbid depressive symptoms. Buspirone is an additional anxiolytic option (Table 79–5) in patients without comorbid depression or other anxiety disorders (e.g., panic disorder and SAD). Because of the high risk of adverse effects and toxicity, barbiturates, antipsychotics, antipsychotic-antidepressant combinations, and antihistamines generally are not indicated in the treatment of GAD.[3] The benzodiazepines are more effective in treating the somatic and autonomic symptoms of GAD as opposed to the psychic symptoms (e.g., apprehension and worry), which are reduced by antidepressants.[3]

TABLE 79-4 Benzodiazepine Antianxiety Agents

Generic Name	Brand Name	Approved Dosage Range (mg/day)[a]	Approximate Equivalent Dose (mg)
Alprazolam[b]	Niravam,[c] Xanax, Xanax XR	0.75–4 1–10[d]	0.5
Chlordiazepoxide[b]	Librium	25–400	10
Clonazepam[b]	Klonopin Klonopin Wafers[c]	1–4[d]	0.25
Clorazepate[b]	Tranxene Tranxene SD	7.5–60	7.5
Diazepam[b]	Valium	2–40	5
Lorazepam[b]	Ativan	0.5–10	1
Oxazepam[b]	Serax	30–120	15

XR, extended-release; SD, sustained-release.
[a]Elderly patients are usually treated with approximately one-half of the dose listed.
[b]Available generically.
[c]Orally disintegrating formulation.
[d]Panic disorder dose.
Equivalent doses from Chouinard.[27]

TABLE 79-5 Nonbenzodiazepine Antianxiety Agents for Generalized Anxiety Disorder

Generic Name	Trade Name	Starting Dose	Dosage Range (mg/day)[a]
Antidepressants			
Duloxetine[b]	Cymbalta	30 or 60 mg/day	60–120
Escitalopram[b]	Lexapro	10 mg/day	10–20
Imipramine[c]	Tofranil	50 mg/day	75–200
Paroxetine[b,c]	Paxil Pexeva	20 mg/day	20–50
Sertraline[c]	Zoloft	50 mg/day	50–200
Venlafaxine XR[b,c]	Effexor XR	37.5 or 75 mg/day	75–225[d]
Azapirone			
Buspirone[b,c]	BuSpar	7.5 mg twice per day	15–60[d]
Diphenylmethane			
Hydroxyzine[b,c,e]	Vistaril	25 or 50 mg 4 times daily	200–400
Anticonvulsant			
Pregabalin	Lyrica	50 mg 3 times daily	150–600
Atypical Antipsychotic			
Quetiapine XR	Seroquel XR	50 mg at bedtime	150–300

XR, extended-release

[a]Elderly patients are usually treated with approximately one-half of the dose listed.

[b]FDA approved for generalized anxiety disorder.

[c]Available generically.

[d]No dosage adjustment is required in elderly patients.

[e]FDA approved for anxiety and tension in children in divided daily doses of 50–100 mg.

Data from Bandelow et al.,[3] Kavouss,[28] Gao et al.,[29] Paxil package insert,[30] Cymbalta package insert,[31] Lexapro package insert,[32] Effexor XR package insert,[33] and Vistaril package insert.[34]

The most recent treatment guidelines from the World Federation of Societies of Biological Psychiatry and the British Association of Psychopharmacology are evidence-based.[3,21] A descriptive flowchart with recommendations based on levels of evidence from the International Psychopharmacology Algorithm Project for the psychosocial and pharmacologic management of GAD is shown in Figure 79–1.[8]

Alternative Drug Treatments

Hydroxyzine, pregabalin, and atypical antipsychotics are alternatives.[8,28,29] The antihistamine hydrozyzine was effective in studies conducted for as long as 12 weeks in patients with GAD. Hydroxyzine is commonly used in the primary care setting, but it is considered be to be a second-line agent because of adverse effects and lack of efficacy for comorbid disorders.[8] Pregabalin, which binds to the $\alpha_2\delta$ subunit of voltage-gated calcium channels to reduce nerve terminal calcium influx, acts on "hyperexcited" neurons. Pregabalin produced anxiolytic effects similar to lorazepam, alprazolam, and venlafaxine in acute efficacy trials.[28] Extended-release quetiapine 150 mg/day monotherapy was superior to placebo in 3 studies, and as effective as paroxetine 20 mg/day and escitalopram 10 mg/day but with an earlier onset of action.[29] In a 52-week treatment of GAD, extended-release quetiapine was superior to placebo in the prevention of anxiety relapse.[29] Quetiapine is not FDA approved for GAD, and the long-term risks and benefits of atypical antipsychotics in the treatment of GAD are unclear.[29] Analysis of data from pooled sample trials found kava-kava to be no more effective than placebo.[35] Because of reports of hepatotoxicity, kava-kava is not recommended as an anxiolytic.[35]

Special Populations

The management of anxiety in patients with substance abuse, pregnant women, children, elderly patients, and those patients with adherence problems requires special consideration in the choice of anxiolytic. Patients with GAD may misuse alcohol, cannabis, or other substances to manage anxiety. The symptoms of GAD are similar to those of withdrawal, and it is difficult to confirm the diagnosis of GAD until after abstinence is obtained. Benzodiazepine therapy should be avoided in this population.

There is evidence that maternal anxiety during pregnancy and the post-partum period potentially pose significant risk to the child. Clinical practice guidelines for anxiety disorders recommend use of fluoxetine, sertraline, or citalopram; however, perinatal syndromes (e.g., jitteriness, myoclonus, irritability) in the neonate and premature delivery have been reported.[21,36] Paroxetine (Category D) should be avoided in pregnant women because of risk of cardiovascular malformations.[30]

Cleft lip, cleft palate, and other teratogenic effects are associated with benzodiazepine use, but a causal relationship is inconclusive. Clinicians should avoid benzodiazepine use during the first trimester, use the lowest dosage for the shortest period of time, divide the total daily dosage into two or three doses to prevent high peak plasma levels, and use the agent as monotherapy.[8,36] Benzodiazepine risks during the third trimester include sedation, withdrawal symptoms, and "floppy" infant syndrome (e.g., hypotonia, low Apgar scores, hypothermia). Alprazolam should be avoided during pregnancy because of neonatal withdrawal. Should benzodiazepines be required during pregnancy, the preferred agents are clonazepam and lorazepam.[8] The antidepressants are favored for GAD during pregnancy based on safety considerations.[36] Diazepam and clonazepam should not be used in nursing mothers because infants can experience sedation, lethargy, and weight loss.[8]

There are few controlled clinical trials of drugs in children and adolescents with GAD. CBT alone or in conjunction with antidepressants can have long-term benefits.[8] Randomized controlled trials of fluovoxamine, fluoxetine, sertraline, and extended-release venlafaxine indicate short-term efficacy;[3,37,38] however, behavioral activation was reported with clonazepam.[3] No antidepressant is FDA-indicated for GAD in children or adolescents. Increased monitoring for behavioral activation with benzodiazepines and suicide-related adverse effects with antidepressants is necessary if these agents are prescribed.

Patients with hepatic disease are at risk for drug accumulation and subsequent complications. Duloxetine use should be avoided in patients with hepatic insufficiency.[31] Drug accumulation can result in the elderly secondary to a decreased capacity for oxidation and alterations in the volume of distribution. Therefore, intermediate- or short-acting benzodiazepines without active metabolites are preferred for chronic use. Elderly patients are also sensitive to the CNS adverse effects of benzodiazepines (regardless of half-life), and use is associated with a high frequency of falls and hip fractures. Venlafaxine, citalopram, duloxetine, and pregabalin showed efficacy in elderly patients with GAD.[3,39]

Antidepressant Therapy

2 Antidepressants are considered first-line agents in the management of GAD. Extended-release venlafaxine, duloxetine, paroxetine, and escitalopram are FDA-approved antidepressants for GAD. Imipramine is considered when patients fail to respond to SSRIs or venlafaxine (see Table 79–5). 3 The anti-anxiety response of antidepressants is delayed by 2 to 4 weeks or longer.[25] The pharmacokinetics and drug interactions of the antidepressants are reviewed in the chapter on depressive disorders (Chapter 77).

Efficacy Antidepressants are efficacious in the acute and long-term management of GAD. Data support the use of SSRIs

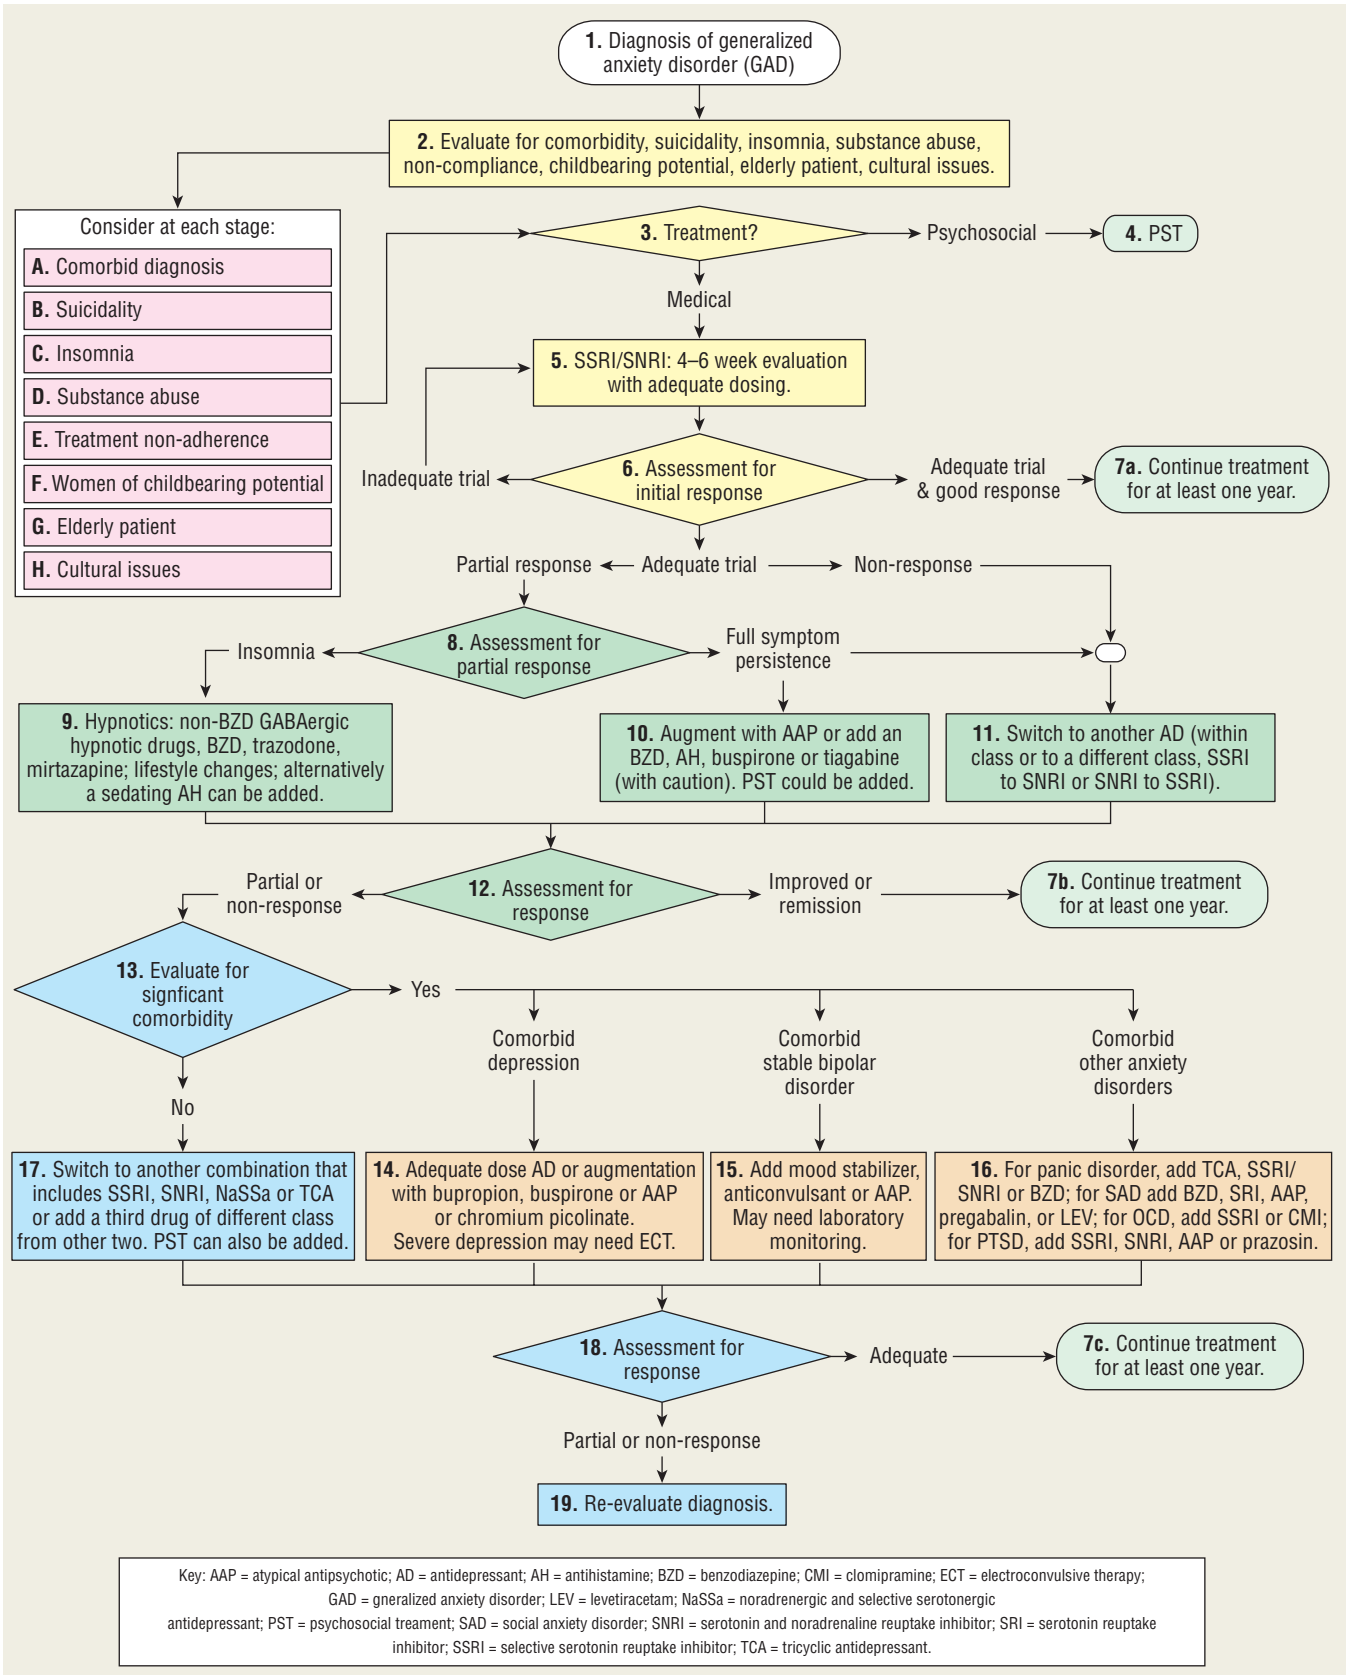

FIGURE 79-1. International Psychopharmacology Algorithm Project (IPAP) Generalized Anxiety Disorder (GAD) Algorithm Flowchart. Yellow, first-line treatment (Nodes 3-6); Green, second-line treatment (Nodes 8-12); Blue, third-line treatment, no comorbidity (Nodes 13-19); Orange, third-line treatment, with comorbidity (Nodes 14-16); Light green, assessment and evaluation. Levels of evidence used in development of the flowchart were: 1 = more than one placebo-controlled trial with sample sizes over 30; 2 = one placebo-controlled trial (or active versus active drug comparison) with sample size of 30 or greater; 3 = one or small ($n < 30$) placebo-controlled trial; 4 = case reports or open-label trials; and 5 = expert consensus without published evidence. *(Flowchart is used by permission of the International Psychopharmacology Algorithm Project, http://www.ipap.org.[8])*

(e.g., escitalopram, paroxetine, sertraline) and SNRIs (e.g., extended-release venlafaxine and duloxetine) for acute therapy (8–12 week trials), with response rates between 60% to 68%, and remission rates of 30%.[3,21] Data show that duloxetine 60 mg and 120 mg daily produce similar remission rates as other antidepressants.[39] In a comparative trial, there was no difference in efficacy between paroxetine and sertraline.[40] Escitalopram 10 mg was superior to paroxetine 20 mg in a fixed-dose study.[41] In a comparative trial, extended-release venlafaxine and escitalopram were both effective for GAD, but escitalopram was better tolerated.[42]

Studies with continued treatment after acute response to SSRIs showed further improvement with escitalopram or paroxetine over 6 months (escitalopram group had fewer withdrawals).[43] Continued venlafaxine therapy was associated with a 62.5% rate of remission.[44] Relapse-prevention studies found that patients continued on paroxetine or escitalopram achieved remission rates of 73% and 65%, respectively.[3,8] In a four parallel-group comparison, diazepam and trazodone were found to be equivalent in anxiolytic activity (remission rates of 66% and 69%, respectively) compared with placebo (47% remission rate), but imipramine's rate of remission (73%) exceeded that of the other three treatments.[37]

Mechanism of Action The mechanism of action of antidepressants in anxiety disorders is not fully understood. Research indicates that antidepressants modulate receptor activation of neuronal signal transduction pathways connected to the neurotransmitters 5-HT, DA, and NE. In an animal model of anxiety, a number of candidate genes were identified that were normalized by fluoxetine treatment selectively in the hypothalamus.[45] It is theorized that by activating stress-adapting pathways, SSRIs and SNRIs reduce the somatic anxiety symptoms and the general distress experienced by patients.

Adverse Effects Paroxetine was associated with a high rate of somnolence, nausea, abnormal ejaculation, dry mouth, decreased libido, and asthenia compared with placebo.[30] Escitalopram caused nausea, insomnia, fatigue, decreased libido, ejaculation disorders, and decreased libido in patients with GAD.[32] The most common adverse events of venlafaxine in patients with GAD were nausea, somnolence, and dry mouth.[33] The use of TCAs can be limited by troublesome adverse events (e.g., sedation, anticholinergic effects, and weight gain) in some patients and the risk of toxicity in overdose.[5] However, in a meta-analysis of antidepressant trials there was no difference in dropout rates between antidepressants (e.g., paroxetine, venlafaxine, and imipramine) compared with placebo, suggesting equivalent tolerability between antidepressants.[37]

Dosing and Administration The antidepressants can be dosed once a day (see Table 79–5). Some patients require small initial daily doses for the first week of therapy. Paroxetine doses greater than 20 mg/day have not been found to be more effective.[30]

Benzodiazepine Therapy

Although all benzodiazepines possess anxiolytic properties, only 7 of the 13 currently marketed agents have FDA approval for the treatment of GAD (see Table 79–4). Estazolam, flurazepam, temazepam, quazepam, and triazolam are marketed as sedative-hypnotic agents. Clonazepam is marketed as an antipanic agent and anticonvulsant,[46] and midazolam is labeled for preoperative sedation. Alprazolam is indicated for the treatment of panic disorder with or without agoraphobia, as well as GAD.[47]

Pharmacology and Mechanism of Action The GABA receptor model of anxiety theorizes that benzodiazepines ameliorate anxiety through potentiation of the inhibitory activity of GABA.[14] Benzodiazepines bind on the $GABA_A$ receptor at the α_1, α_2, α_3, and α_5 subunits in combination with a β subunit and the γ_2 subunit.[14] The anxiolytic effects of benzodiazepines are mediated at the α_2 site while sedative effects result from binding at the α_1 subunit. The binding sites of benzodiazepines and GABA are at the receptor interfaces of α/β and α/γ_2, respectively. The GABA receptor controls tonic inhibition to reduce neuronal excitability.[14] Other neurotransmitters (e.g., 5-HT, NE, and DA) may also be involved in benzodiazepine activity.

Pharmacokinetics A wide difference in milligram potency exists between the benzodiazepine compounds; however, when appropriately dosed, all agents have similar anxiolytic and sedative-hypnotic activity. The variations in lipid solubility between compounds influence the pharmacokinetic properties of benzodiazepines. Knowledge of the different pharmacokinetic and pharmacodynamic properties can assist in choosing an appropriate anxiolytic (Table 79–6). After a single dose, the onset, intensity, and duration of pharmacologic effects are important factors to consider when using benzodiazepines for the short-term, intermittent, or as-needed treatment of anxiety.

The primary determinant of a drug's onset of effect after a single oral dose is the rate of drug absorption. Because of high lipophilicity, diazepam and clorazepate are absorbed rapidly and distributed quickly into the CNS. Therefore the onset of anxiolytic effect occurs within 30 to 60 minutes, which results in a rapid and intense relief of anxiety. High lipophilicity also increases the extent of drug redistribution into the periphery, particularly adipose tissue, resulting in a shorter duration of effect after a single dose than suggested by single-dose elimination

TABLE 79-6 Pharmacokinetics of Benzodiazepine Antianxiety Agents

Generic Name	Time to Peak Plasma Level (h)	Elimination Half-Life, Parent (h)	Metabolic Pathway	Clinically Significant Metabolites	Protein Binding (%)
Alprazolam	1–2	12–15	Oxidation	–	80
Chlordiazepoxide	1–4	5–30	*N*-Dealkylation Oxidation	Desmethylchlordiazepoxide Demoxepam DMDZ[a]	96
Clonazepam	1–4	30–40	Nitroreduction	–	85
Clorazepate	1–2	Prodrug	Oxidation	DMDZ	97
Diazepam	0.5–2	20–80	Oxidation	DMDZ Oxazepam	98
Lorazepam	2–4	10–20	Conjugation	–	85
Oxazepam	2–4	5–20	Conjugation	–	97

[a]Desmethyldiazepam (DMDZ) half-life 50–100 h.
Data from Rosenbaum et al.,[48] and Facts and Comparisons.[49]

half-life studies.[48] Clinically, patients perceive a rapid onset of action, but some experience an unpleasant feeling of drowsiness or loss of control. This "rush" can be euphoric and contribute to abuse.

Compared with diazepam, lorazepam and oxazepam are relatively less lipophilic and have a slower absorption and onset of effect. These benzodiazepines have smaller volumes of distribution and a resulting longer duration of action.[48]

Parenteral administration via the intramuscular route should be avoided with diazepam and chlordiazepoxide secondary to variability in the rate and extent of drug absorption. Intramuscular lorazepam provides rapid, reliable, and complete absorption.

After multiple dosing, the rate and extent of drug accumulation are functions of the drug's elimination half-life in relation to dosing intervals, clearance, and formation of active metabolites. Differences in clinical effects that occur during and after repeated dosages with the benzodiazepines are related in part to variability in metabolism and metabolite accumulation.[48]

The benzodiazepines undergo two primary metabolic processes, hepatic oxidation (catalyzed by cytochrome P450 3A4) and glucuronide conjugation. With the exception of lorazepam and oxazepam (which are conjugated only) and clonazepam (which undergoes nitroreduction), all benzodiazepines are oxidized first and then conjugated and excreted renally.[48] Diazepam's metabolism is also catalyzed by cytochrome P450 2C19. Oxidation can be impaired in patients with liver disease, in the elderly, and in those who simultaneously use drugs that inhibit oxidation resulting in higher levels of the parent drug and/or an active metabolite.

Many benzodiazepines are converted to desmethyldiazepam (DMDZ), an active metabolite with a long elimination half-life[48] (Table 79–6). DMDZ is further oxidized to oxazepam and then conjugated and excreted. After multiple dosing, accumulation of DMDZ is slow and extensive, providing a long-lasting antianxiety effect. If oxidation of DMDZ is impaired, the half-life is prolonged, and extensive drug accumulation can result with repeated dosing.

Clorazepate is a prodrug and possesses no anxiolytic effects until metabolized to DMDZ. Before absorption, clorazepate is metabolized rapidly in the stomach through a pH-dependent process under acidic conditions.

Benzodiazepines with shorter half-lives (e.g., alprazolam, lorazepam, and oxazepam) reach steady-state plasma concentrations rapidly, and drug accumulation after repeated dosing is minimal. Oxazepam and lorazepam have no active metabolites.

Benzodiazepine protein binding is extensive, especially for the drugs with a long elimination half-life. After a single dose of a benzodiazepine with a long elimination half-life, the expected duration of clinical activity may not parallel the drug's pharmacokinetic half-life because of drug redistribution.[48] After multiple dosing, drugs with long elimination half-lives and active metabolites require 1 to 2 weeks to reach steady state.

Efficacy Clinical trials of benzodiazepines show that 65% to 75% of patients with GAD have a marked to moderate response, with most of the improvement occurring in the first 2 weeks of therapy. Benzodiazepines are more effective on the somatic symptoms of anxiety and fail to obviate the cognitive or psychic symptoms (e.g., worry).[11,25] Up to 50% of patients fail to reach remission with benzodiazepine therapy, and rates of relapse exceed that of the antidepressants.[25]

Adverse Effects The most common adverse events associated with benzodiazepine therapy involve CNS depression. This is manifested clinically as drowsiness, sedation, psychomotor impairment, and ataxia.[25] A transient mild drowsiness is experienced commonly by patients during the first few days of treatment; however, tolerance often develops. Disorientation, depression, confusion, irritability, aggression, and excitement are reported.[25]

Impairment of memory and recall also can occur during benzodiazepine treatment. The memory loss induced by the benzodiazepines typically is limited to events occurring after drug ingestion (anterograde amnesia).[25,27,49] Anterograde amnesia is secondary to disordered consolidation processes that store information and is not impairment in the perception or retrieval of information.[2] Benzodiazepines with high affinity for binding to the benzodiazepine receptor (e.g., alprazolam) appear to possess a higher potential for amnesia.[27]

Abuse, Dependence, Withdrawal, and Tolerance Two serious complications of benzodiazepine therapy are the potential for abuse and development of physical dependence. Benzodiazepine abuse is rare in the general population of users; however, individuals with a history of multiple drug abuse (e.g., alcohol or sedatives) are at the greatest risk for becoming benzodiazepine abusers.[5]

Because of the chronicity of illness, persons with GAD and panic disorder are at high risk of developing benzodiazepine dependence. Benzodiazepine dependence is a physiologic phenomenon demonstrated by the appearance of a predictable abstinence syndrome (withdrawal symptoms) on abrupt discontinuation of therapy.[27] Withdrawal symptoms can result because of the sudden dissociation of a benzodiazepine from its receptor site. After abrupt discontinuation, an acute decrease in GABA neurotransmission results, producing a less inhibited CNS.

Benzodiazepine Discontinuation After benzodiazepine therapy is discontinued suddenly, several events can occur. Rebound anxiety represents an immediate but transient return of original symptoms having an increased intensity compared with baseline. Recurrence or relapse is the return of original symptoms with similar intensity as before treatment.

Withdrawal symptoms are the emergence of new symptoms and a worsening of preexisting symptoms after benzodiazepine discontinuation. Symptoms can persist for days to weeks and resolve gradually over months.

Common symptoms of benzodiazepine withdrawal include anxiety, insomnia, restlessness, muscle tension, and irritability. Less frequently occurring symptoms are nausea, malaise, coryza, blurred vision, diaphoresis, nightmares, depression, hyperreflexia, and ataxia. Tinnitus, confusion, paranoid delusions, hallucinations, and seizures occur rarely. Seizures can occur with both therapeutic and high doses of benzodiazepines with a short elimination half-life, usually within 3 days of drug discontinuation. They can occur approximately 1 week after discontinuation of agents with a long elimination half-life. High benzodiazepine doses, a long duration of therapy, and concurrent ingestion of drugs that lower the seizure threshold are risk factors for withdrawal seizures.

The onset of withdrawal symptoms in patients ingesting benzodiazepines with short elimination half-lives occurs much earlier (within 24–48 hours) than in those taking benzodiazepines with long elimination half-lives (within 3–8 days). Other factors associated with an increased incidence and severity of benzodiazepine withdrawal include high doses and long-term benzodiazepine therapy.

A strategy to minimize the severity of benzodiazepine withdrawal is a 25% per week reduction in dosage until 50% of the dose is reached, and then dosage reduction by one-eighth every 4 to 7 days.[27] If therapy exceeds 8 weeks, a slow dosage taper over 2 to 3 weeks is recommended; however, if the duration of treatment is 6 months, a taper over 4 to 8 weeks should ensue.[5] Long-term use of benzodiazepines (i.e., 1 year or longer) requires a 2- to 4-month slow taper.[5] Tapering will not eliminate the emergence of withdrawal symptoms entirely but will prevent severe withdrawal. Slow drug taper is extremely important for the drugs with a short elimination half-life, because some individuals have greater difficulty with discontinuation.

Withdrawal symptoms with short half-life benzodiazepines were no more severe than with longer half-life agents, therefore switching from a short- to long-acting benzodiazepine before gradual taper is not supported.[50,51] Adjunctive use of carbamazepine can help reduce withdrawal severity during the benzodiazepine taper.[50,51] Patients should avoid the intake of alcohol and stimulants during the withdrawal process. Although tolerance develops to the sedative, muscle relaxant, and anticonvulsant activities, the benzodiazepines do not appear to lose anxiolytic or antipanic efficacy. The anxiolytic efficacy of benzodiazepines in long-term clinical trials (greater than 6–8 months of chronic use) has not been reported.[5]

Drug Interactions Drug interactions with the benzodiazepines generally fall into two categories: pharmacodynamic and pharmacokinetic. Simultaneous use of alcohol and a benzodiazepine results in additive CNS depressant effects. In addition, concurrent use of a benzodiazepine and other drugs with CNS depressant properties (e.g., opioids, antipsychotics, and antihistamines) can potentiate the adverse sedative effects. When ingested alone in an overdose attempt, benzodiazepines are rarely life-threatening; however, the combination of benzodiazepines with alcohol or other CNS depressant agents is potentially fatal.

Concurrent use of medications that inhibit cytochrome P450 3A4 (e.g., ketaconazole, nefazodone, and ritonavir) can increase the blood levels of alprazolam and diazepam. Drugs that induce cytochrome P450 3A4 (e.g., carbamazepine, St. John's wort) can reduce benzodiazepine levels. Consult a drug interaction Website (e.g., *http://online.factsandcomparisons.com*) for further information.

Dosing and Administration Benzodiazepine dosage requirements vary widely among patients and must be individualized. Therapy should be initiated using low doses (e.g., alprazolam 0.25 mg 3 times a day or equivalent doses of other benzodiazepines) and titrated upward to relieve anxiety symptoms and avoid adverse events. After an initial treatment response is achieved, agents with long elimination half-lives can be dosed at bedtime. Dosage adjustments should be made weekly. Three to four weeks of a daily dose at the maximum dose constitutes an adequate clinical trial (see Table 79–4).[5]

The duration of benzodiazepine therapy for the acute management of anxiety should be limited to 2 to 4 weeks. In general, benzodiazepines should be used with a regular dosing regimen and not on an as-needed basis.[8] Only in the treatment of short-term distress (e.g., air travel, dental phobia) as-needed use may be justified.[3,8] Individuals with persistent symptoms should be managed with antidepressants because of the risk of dependence with continued benzodiazepine therapy.[25]

Patient education should include the anticipated length of drug therapy, potential side effects, and consequences of the ingestion of alcohol and other CNS depressants. Patients should understand that benzodiazepines provide symptomatic relief but do not solve underlying psychologic problems. Patients should be instructed not to decrease or discontinue benzodiazepine usage without contacting their prescriber.

Buspirone Therapy

Buspirone is a nonbenzodiazepine anxiolytic that lacks anticonvulsant, muscle relaxant, hypnotic, motor impairment, and dependence properties. It is considered to be a second-line agent for GAD because of inconsistent reports of efficacy (particularly long term), delayed onset of effect (i.e., 2 weeks or longer), and lack of efficacy for other potential concurrent depressive and anxiety disorders.[21,52] Unlike benzodiazepines, buspirone is effective for the psychic symptoms of anxiety.[52]

Pharmacology and Mechanism of Action Buspirone's anxiolytic mechanism of action is unknown. It is thought to exert its anxiolytic effect through partial agonist activity at the 5-HT_{1A} presynaptic receptors, thus reducing the firing of 5-HT neurons.[52]

Pharmacokinetics After an oral dose, buspirone is absorbed rapidly and completely and undergoes extensive first-pass metabolism. The mean elimination half-life is 2.5 hours, and it must be dosed 2 to 3 times daily, which adversely affects adherence to the drug regimen.[25]

Adverse Effects Adverse events include dizziness, nausea, and headaches.[25]

Drug Interactions Drugs that inhibit cytochrome P450 3A4 (e.g., verapamil, itraconazole, fluvoxamine) can increase buspirone levels. Rifampin caused a 10-fold reduction in buspirone levels. Buspirone reportedly elevates blood pressure in patients taking a monoamine oxidase inhibitor (MAOI).

Dosing and Administration The dose of buspirone can be titrated in increments of 5 mg/day every 2 to 3 days as needed.[25] The onset of improvement in psychic symptoms precedes the relief of somatic symptoms; maximum therapeutic benefit might not be evident for 4 to 6 weeks.

Buspirone is a treatment option for patients with GAD, particularly for patients with uncomplicated GAD, in patients who fail other anxiolytic therapies, or in patients with substance abuse. It is not useful in clinical situations requiring immediate anxiolysis or for patients requiring as-needed anxiolytic therapy.[52] The use of benzodiazepines within the month previous to initiation of buspirone therapy was associated with reduced efficacy of buspirone because of its delayed onset in the reduction of somatic symptoms.[25]

PHARMACOECONOMIC CONSIDERATIONS

The total annual cost of anxiety disorders has been estimated to be between $42.3 billion and $46.6 billion, of which more than 75% can be attributed to morbidity, mortality, lost productivity, and other indirect costs.[53] The total cost estimate for anxiety disorders comprises more than 30% of the total expenditures for mental illnesses; the cost of anxiety drug therapy accounts for 53% of the drug expenditures for mental illnesses.[53]

GAD is associated with high rates of healthcare use and disability. The number of days missed from work increases when GAD is concurrent with one or more other psychiatric disorders. Patients with GAD tend to use family practitioners and gastroenterologists more frequently than healthy controls.[54] GAD ranks third among anxiety disorders in the rate of use of primary care physician time, and it is the leading cause of disability in the workplace in the United States.[54] Two decision analyses for GAD were published by researchers in the United Kingdom: venlafaxine was more cost-effective than diazepam,[55] and escitalopram was associated with higher treatment success and lower discontinuation rates and costs than paroxetine.[56]

CLINICAL CONTROVERSY

It is unclear if combining pharmacotherapy with CBT in patients with GAD confers greater overall efficacy than treatment with either approach alone. CBT is an option if patients fail consecutive antidepressant trials, however many patients lack access to CBT.

EVALUATION OF THERAPEUTIC OUTCOMES

Initially, anxious patients should be monitored once every 2 weeks[21] for a reduction in the frequency, duration, and severity of

anxiety symptoms and improvement in functioning. The clinician should assess the patient for response to treatment by asking about specific target symptoms of anxiety and emergence of adverse events. Ideally, the patient should have no or minimal anxiety or depressive symptoms and no functional impairment. Use of an objective measurement of remission of GAD (e.g., Hamilton Rating Scale for Anxiety score less than or equal to 7 and a Sheehan Disability Scale score less than or equal to 1 on each item) can assist in the evaluation of drug response.[8,25] The definition of treatment resistance is defined as a poor, partial, or lack of response with at least two antidepressants from different classes. Treatment strategies for patients who do not achieve an appropriate response with a first-line agent include increasing the dose of the SSRI/SNRI; changing to a different agent in the same class; changing to a different agent of a different class; or augmentation of therapy.[5,8] At any point of nonresponse or loss of previous response, the clinician should assess for symptoms that may suggest a need for additional new medications, cause treatment nonadherence, or change management (e.g., suicidal thoughts, psychotic symptoms, substance abuse).[8] Once a patient has responded to pharmacotherapy, the regimen should be continued for at least 1 year.[8] Early discontinuation is associated with a greater risk of relapse.[8]

TREATMENT

Panic Disorder

DESIRED OUTCOME

The goal of therapy in panic disorder is remission. Patients should be free of panic attacks, have no or minimal anticipatory anxiety and agoraphobic avoidance, and no functional impairment.[26] Naturalistic studies indicate that after pharmacotherapy, over 50% of patients have occasional panic attacks, 40% experience agoraphobic avoidance, and most continue to take medications.[57]

GENERAL APPROACH TO TREATMENT

Therapeutic options include single or combined pharmacologic agents, concurrent psychotherapy, or psychotherapy followed by pharmacotherapy. Most patients without agoraphobic avoidance will improve with pharmacotherapy alone; however, if avoidance is present, CBT typically is initiated concurrently. With all effective drug therapies, resolution of agoraphobic avoidance tends to occur slowly. A meta-analysis of 11 randomized clinical trials comparing the use of SSRIs, TCAs, and CBT showed the effect on global anxiety and response to be similar among all treatments.[58]

In the most comprehensive study to date, efficacy of imipramine alone and CBT alone were equivalent in acute therapy for 3 months and during 6 months of maintenance therapy. Combined imipramine and CBT therapy was not significantly better than CBT or imipramine alone for acute therapy but was significantly better during maintenance. At 6 months after discontinuation, only patients previously treated with CBT maintained improvement (4% relapse) compared with a 25% relapse rate in patients previously treated with imipramine.[59] Adding psychosocial treatment to pharmacotherapy may improve long-term outcomes by reducing the likelihood of relapse when pharmacotherapy is stopped.[26]

NONPHARMACOLOGIC THERAPY

Patients should be educated to avoid substances that can precipitate panic attacks, including caffeine, nicotine, alcohol, drugs of abuse, and nonprescription stimulants.[1,26] Epidemiologic data suggest that daily smoking increases risk for panic attacks and may be a causal or exacerbating factor in some individuals with panic disorder.[57] Preliminary evidence suggests that aerobic exercise (e.g., walking for 60 minutes or running for 20–30 minutes 4 days/week) may benefit patients with panic disorder.[26] CBT is associated with short-term improvement in 80% to 90% of patients and 6-month improvement in 75% of patients. A course of CBT for panic disorder is 16 to 20 hours in length conducted over a period of 4 months.[60] Bibliotherapy (the use of self-help books), exercise, and Internet-based CBT are other options.[21,26]

PHARMACOLOGIC THERAPY

Panic disorder is treated effectively with several drugs including SSRIs, the TCA imipramine, and the benzodiazepines alprazolam and clonazepam[3,22,61] (Table 79–7). Alprazolam, clonazepam, sertraline, paroxetine, and venlafaxine are approved for this indication. SSRIs are the first-line agents because of their tolerability and efficacy in acute and long-term studies;[3,26,57] however, the benzodiazepines are the most commonly used drugs for panic disorder.[26] In a meta-analysis of the pharmacotherapy of panic disorder, the effect size of SSRIs and TCAs did not differ; however, the number of dropouts in the TCA group (31%) was significantly higher than in the SSRI group (18%).[57] A second meta-analysis comparing efficacy of benzodiazepines, TCAs, and SSRIs in panic disorder concluded that all treatments were equally efficacious with 50% to 80% of patients responding to treatment; however benzodiazepines were less effective for depression.[58] A long-term comparison study of SSRIs (e.g., citalopram, fluoxetine, fluvoxamine, paroxetine) found an equal overall response rate after 4 weeks of treatment. However, acute and long-term adverse effects differed between the drugs.[62] Five practice guidelines have been published.[3,22,26,60,63] An algorithm for the pharmacologic therapy of panic disorder appears in Figure 79–2.

TABLE 79-7 Drugs Used in the Treatment of Panic Disorder

Class/Generic Name	Brand Name	Starting Dose	Antipanic Dosage Range (mg)
Selective serotonin reuptake inhibitors			
Citalopram[a]	Celexa	10 mg/day	20–60[b]
Escitalopram	Lexapro	5 mg/day	10–20[b]
Fluoxetine[a]	Prozac	5 mg/day	10–30[b]
Fluvoxamine[a]	Luvox	25 mg/day	100–300[b]
Paroxetine[a]	Paxil	10 mg/day	20–60[c]
	Pexeva		
	Paxil CR	12.5 mg/day	25–75[c]
Sertraline[a]	Zoloft	25 mg/day	50–200[c]
Serotonin norepinephrine reuptake inhibitor			
Venlafaxine XR[a]	Effexor XR	37.5 mg/day	75–225[c]
Benzodiazepines			
Alprazolam[a]	Xanax	0.25 mg 3 times a day	4–10[c]
	Xanax XR	0.5–1 mg/day	1–10[c]
Clonazepam[a]	Klonopin	0.25 mg once or twice per day	1–4[c]
Diazepam[a]	Valium	2–5 mg 3 times a day	5–20[b]
Lorazepam[a]	Ativan	0.5–1 mg 3 times a day	2–8[b]
Tricyclic antidepressant			
Imipramine[a]	Tofranil	10 mg/day	75–250[b]
Monoamine oxidase inhibitor			
Phenelzine	Nardil	15 mg/day	45–90[b]

[a]Available generically.
[b]Dosage used in clinical trials but not FDA approved.
[c]Dosage is FDA approved.
Data from Bandelow et al.[3] Katon,[22] and American Psychiatric Association.[26]

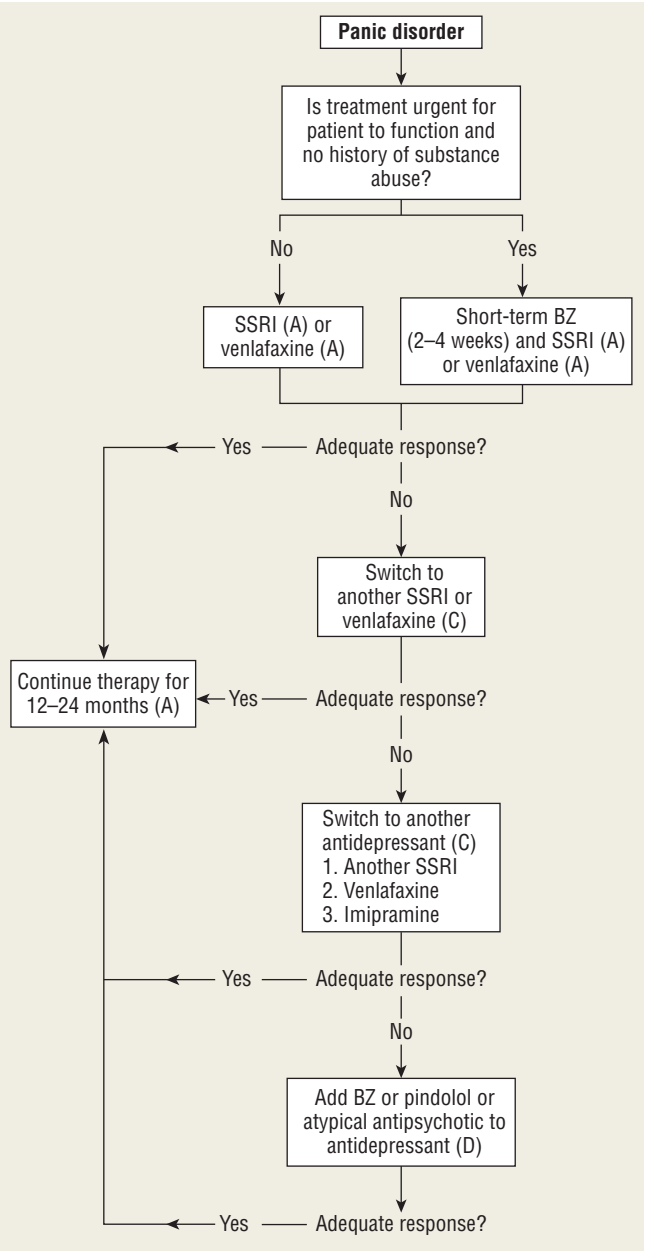

FIGURE 79-2. Algorithm for the pharmacotherapy of panic disorder. Strength of recommendations: A = directly based on category I evidence (i.e., meta-analysis of randomized controlled trials [RCT] or at least one RCT); B = directly based on category II evidence (i.e., at least one controlled study without randomization or one other type of quasi-experimental study); C = directly based on category III evidence (i.e., nonexperimental descriptive studies); D = directly based on category IV evidence (i.e., expert committee reports or opinions and/or clinical experience of respected authorities). (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor.) *(Data from APA[26] and NICE.[60])*

The efficacy of antidepressants was demonstrated in acute and long-term trials. Three 12-week, acute trials compared antidepressants. Escitalopram, but not citalopram, reduced the frequency of panic attacks although both improved QOL and reduced disease severity.[64] There was no difference in outcomes between paroxetine 40 to 60 mg and sertraline 50 to 150 mg daily.[65] Extended-release venlafaxine (75 mg or 150 mg) and paroxetine 40 mg achieved a 44% remission rate compared with that of placebo (24%).[66] Double-blind trials indicated that continuing sertraline, citalopram, or imipramine from 3 months to 1 year improved response rates.[22] Relapse prevention trials with fluoxetine, imipramine, paroxetine, sertraline, and extended-release venlafaxine resulted in reduced relapse rates compared with placebo.[21,26]

Benzodiazepines are considered second-line agents. Because of the risk of dependency, benzodiazepines should be used only after several trials of antidepressants have failed.[3,26] Because of potential emergence of depressive symptoms during treatment, benzodiazepines should not be used as monotherapy in a patient who is clinically depressed or has a history of depression. In patients whose illness is complicated by a history of alcohol or drug abuse, benzodiazepine use should be avoided.[26] Controlled trials have established that the short-term (4–6 weeks) addition of alprazolam or clonazepam to antidepressants produces a more rapid therapeutic response, with discontinuation of the benzodiazepine by week 7 of therapy.[63]

Alternative Drug Treatments

Buspirone, trazodone, bupropion, antipsychotics, antihistamines, and β-blockers are ineffective in panic disorder.[3,21,26] The majority of studies assessing the efficacy of MAOIs in treating panic disorder were open labeled and lacked adequate sample sizes. MAOIs are reserved for the most refractory or difficult patients.[21]

Special Populations

Elderly patients with panic disorder have fewer, less intense symptoms and avoidant behavior than younger patients.[67] Youth often present with fear that they are dying or being smothered, and agoraphobia can be manifested as a fear of leaving home.[68] CBT is effective in both populations. If pharmacotherapy is used, antidepressants, especially SSRIs, are preferred for management of panic disorder, and benzodiazepines are second-line agents because of potential problems with disinhibition in these two populations.

Antidepressant Therapy

Tricyclic Antidepressants

Efficacy Imipramine is the most studied TCA, alleviating panic attacks in 75% of patients with panic disorder. Imipramine effectively blocks panic attacks within at least 4 weeks; however, maximal improvement (including antiphobic response) does not occur until 8 to 12 weeks.[26]

Adverse Effects Up to 40% of patients experience stimulant-like side effects, including anxiety, insomnia, and jitteriness.[26] These side effects often affect patient compliance, prevent medication dosage increases, and interfere with the overall treatment outcome.

Other problems with TCA use in panic disorder are well documented and include anticholinergic effects, orthostatic hypotension, delayed onset of antipanic effects, and toxicity in overdose.[26] Approximately 25% of patients reportedly discontinue treatment because of side effects, especially weight gain.[26]

Dosing and Administration When using imipramine, treatment should be slowly increased by 10 mg every 2 to 4 days as tolerated.

Selective Serotonin Reuptake Inhibitors

Efficacy Clinical studies indicate that all SSRIs are effective in panic disorder.[21,26,57,58,69] The percentage of patients who become panic-free ranges between 60% and 80%.[26] 4 The antipanic effect of SSRIs is delayed for at least 4 weeks, and some patients do not respond for 8 to 12 weeks.[26]

Adverse Effects Typical antidepressant doses of SSRIs can cause side effects of insomnia, jitteriness, restlessness, and agitation, and lead to drug discontinuation in patients with panic disorder. Transient gastrointestinal disturbances occur more frequently with SSRIs than with TCAs. Thus low initial SSRI doses should be

prescribed.[26,58,69] Sleep disturbances, headaches, weight gain, and sexual dysfunction often are problematic.[26,57]

Dosing and Administration Low initial doses of SSRIs are recommended (see Table 79–7) to avoid stimulatory side effects (e.g., insomnia or nervousness), and should be maintained for the first week of therapy. Doses at the upper end of the dosing range can be necessary to achieve response.[60]

Serotonin Norepinephrine Reuptake Inhibitors

Efficacy Approximately 54% to 60% of patients were panic-free on extended-release venlafaxine 75 mg or 150 mg daily. The remission rates were 44% for both dosages in acute efficacy studies.[65]

Adverse Effects The most common adverse effects of extended-release venlafaxine in panic trials were nausea, somnolence, tremors, sweating, and abnormal sexual functioning.[33]

Dosing and Administration The dosage of venlafaxine can be increased at weekly intervals. A dose-response relationship was not evident in clinical trials.[33]

Benzodiazepines

Efficacy The high-potency benzodiazepines clonazepam and alprazolam are the preferred agents.[26,57] Diazepam and lorazepam are possibly effective in treating panic disorder when taken in sufficiently high doses.[26] Alprazolam is an ideal agent for patients who need rapid relief. Therapeutic response to benzodiazepines occurs in 1 to 2 weeks. Relapse rates of 50% or higher are common despite slow drug tapering.[51]

Adverse Effects Patient acceptance of benzodiazepines usually is not a problem, and except for sedation, side effects are reported rarely.

Dosing and Administration Doses of clonazepam can be increased by 0.25 or 0.5 mg every 3 days to 4 mg/day if needed.[46] Alprazolam can be slowly increased over several weeks to reach an ideal dose. 5 The duration of action of immediate-release alprazolam can be as little as 4 to 6 hours with resulting breakthrough symptoms; use of the extended-release alprazolam or clonazepam will avoid this problem. Most patients require 3 to 6 mg/day of alprazolam, and some need higher doses to obtain a full therapeutic (antipanic and antiphobic) response.

Treatment Resistance Common reasons for treatment failures are comorbid psychiatric disorders, rapid dosage increases with resulting intolerable side effects, and underdosage.[26] All standard treatments should be tried before using augmentation strategies. In patients with a partial response to one agent, a low dose of another antipanic agent (e.g., a TCA, benzodiazepine, or an SSRI) can be added.[26]

Phases of Therapy

Acute Phase The main goal of therapy in the acute phase is reduction of symptoms (e.g., resolution of panic attacks, reduction in anxiety and phobic fears, resumption of the patient's usual activities).[21] The duration of this phase is generally 1 to 3 months depending on the choice of drug. Therapy should be altered if there is no response after 6 to 8 weeks of an adequate dose.

The guiding principle for SSRI and SNRI drugs in panic disorder is to start with low doses (approximately one-quarter to one-half of the starting doses for depression), use an adequate dose, and treat for about 12 weeks.[21] Side effects with the antidepressants, often from too high an initial dose, can prevent achievement of an optimal dosage, compromise treatment response, and contribute to patient nonadherence.

The duration of the acute phase with benzodiazepines is approximately 1 month because response is rapid. A regular dosing schedule rather than an as-needed schedule is preferred for patients with panic disorder who are taking benzodiazepines, where the goal is to prevent panic attacks rather than reduce symptoms once an attack has already occurred.[26]

Maintenance Phase and Discontinuation 6 The optimal length of therapy is unknown; however, the total duration of therapy appears to be 12 to 24 months before drug discontinuation over 4 to 6 months is attempted.[26] The dose used in the acute phase is continued into the maintenance phase.[26] Citalopram, clomipramine, fluoxetine, sertraline, venlafaxine, and imipramine have been shown to maintain clinical effects for up to 1 year of treatment.[3,21] When drugs are discontinued too early, a high rate of relapse occurs; thus longer periods of treatment are associated with a more sustained response. Reinstitution of drug usually results in renewed clinical response.[26] Pharmacotherapy, even at long duration, might not prevent relapse, and many patients require long-term therapy.

The most important determinant of adherence with maintenance therapy is the tolerability of adverse events.[26] Some adverse events which are experienced short term become unbearable during long-term management (e.g., sexual dysfunction and weight gain). TCAs, SSRIs (except fluoxetine), and venlafaxine can be associated with discontinuation symptoms.

The primary risk of long-term benzodiazepine use is the development of dependency and withdrawal reactions on discontinuation. Abuse of benzodiazepines usually is confined to patients with a personal or family history of substance or alcohol use.[5,26,69] The approach to benzodiazepine discontinuation involves a slow and gradual tapering of the dose because withdrawal symptoms and rebound anxiety may occur during discontinuation. Benzodiazepines should be tapered over 2 to 4 months at rates no higher than 10% of the dose per week.[26]

Providing education about the disorder may relieve some of the symptoms of panic by helping the patient to realize that the symptoms are neither life-threatening nor uncommon. Patients should be informed regarding the lag time before a therapeutic response will occur and any problematic side effects. Many patients are reluctant to take drugs for fear that their illness will worsen or that they will become addicted. Adverse events are often perceived as a worsening of the illness and can contribute to nonadherence or prevent necessary dosage increases. Patients receiving benzodiazepines and antidepressants should be told not to decrease or discontinue therapy unless authorized by their clinician.[60]

PHARMACOECONOMIC CONSIDERATIONS

Patients with panic disorder have high rates of unemployment and receive welfare, disability benefits, and healthcare services.[3,26,57] They also have impaired emotional and physical health status and experience poor marital and social functioning.[21,22] Measures of QOL improved with imipramine, clonazepam, sertraline, and venlafaxine. Treatment with clomipramine, paroxetine, or fluoxetine improved work, social, and family responsibilities. Improvements in anxiety and phobic avoidance were significantly associated with QOL improvements.[21,22] In a cost-efficacy evaluation of individual and combined treatments for panic disorder, imipramine was the most cost-efficacious treatment option at the completion of the acute phase. CBT was the most cost-efficacious option at the end of maintenance treatment and 6 months after treatment termination.[70]

CLINICAL CONTROVERSY

The cognitive effects of benzodiazepines are a subject of debate. Benzodiazepines at higher doses can cause memory impairment. One meta-analysis reported that long-term benzodiazepine users performed worse than controls on domains of cognitive functioning. However, another review concluded that the literature does not provide evidence of long-term cognitive effects of benzodiazepines in patients with anxiety.

EVALUATION OF THERAPEUTIC OUTCOMES

During the first few weeks of the acute phase of therapy, patients with panic disorder should be seen every 1 to 2 weeks when starting a new medication, then every 2 to 4 weeks to adjust drug dosages based on improvement in panic symptoms and to monitor for adverse events.[60] After the dose is stabilized and symptoms have decreased, visits every 2 months should suffice.[60] The patient should be counseled to maintain a diary to record the date, time, frequency, duration, and intensity of panic episodes, level of anticipatory anxiety or agoraphobic avoidance, and the severity of distress and impairment related to panic disorder. Treatment outcomes can be assessed objectively by use of the Panic Disorder Severity Scale. Remission is defined as equal to or less than 3 with no or mild agoraphobic avoidance, anxiety, disability, or depressive symptoms. Treatment response is indicated by a 40% or greater reduction in overall score.[63]

At scheduled visits, the clinician can inquire about the level of disability experienced by the patient and have the patient complete the Sheehan Disability Scale (with a goal of less than or equal to 1 point on each item).[71] During drug discontinuation, the frequency of appointments should be increased to evaluate for emergence of potential withdrawal symptoms and monitor for relapse.

TREATMENT

Social Anxiety Disorder

DESIRED OUTCOME

The goals of therapy in the acute phase of treatment are to reduce physiologic symptoms of anxiety (e.g., tachycardia, flushing, and sweating), social anxiety, and phobic avoidance. The duration of this phase is 4 to 12 weeks, depending on the drug therapy.

The goals of therapy in the continuation phase (3–6 months) are to extend the therapeutic benefits, especially the patient's ability to participate in social activities, and improve QOL. Although the primary goal of treatment is to reduce anxiety symptoms to manageable levels, even modest reductions in avoidance and discomfort can be highly valued by patients.[24]

7 At least a 1-year maintenance period is recommended to maintain improvement and decrease the rate of relapse.[17,63] Situations suggesting a possible need for long-term treatment include the presence of unresolved symptoms or comorbidity, an early onset of disease, and a prior history of relapse.[24] The long-term goal in the treatment of SAD is remission with the disappearance of the core symptoms of social anxiety, little or no anxiety, and no functional impairment or concurrent depressive symptoms.[71]

GENERAL APPROACH TO TREATMENT

Patients with generalized SAD should be treated aggressively. Obstacles to effective treatment include patient avoidance of therapy secondary to fear and shame, treatment directed toward somatic symptoms or concurrent conditions, and financial barriers.[17] Patients with SAD often respond more slowly and less completely than patients with other anxiety disorders. Therefore, it is important to set reasonable expectations for response to therapy. Consideration of current symptoms, prior treatments, concurrent conditions, and history of substance abuse guide treatment selection.

CBT and pharmacotherapy are effective in the treatment of SAD.[17,24,72,73] Pharmacotherapy is often the most practical choice because CBT might not be available outside of large urban areas. Acute treatment outcomes for CBT and pharmacotherapy are equal.[17,24] Drug therapy is superior in reducing subjective general anxiety acutely, although CBT has a greater likelihood of maintaining response after termination.[24,74]

There are no data to predict which patients will respond best to pharmacotherapy, CBT, or a combination[24] or maintain gains after discontinuing pharmacotherapy. The only significant indication of treatment response in pharmacotherapy is duration of treatment.[24] Some patients elect lifelong therapy, and many are reluctant to attempt drug discontinuation because of fear of relapse. Discontinuation of drug therapy after only 2 to 3 months resulted in higher rates of relapse than when therapy was continued for 5 to 12 months.[24] Data show that relapse rates after discontinuation of CBT are significantly less than those after discontinuation of effective pharmacotherapy.[17,24] Sertraline is the only medication approved for the long-term treatment of SAD, although paroxetine, escitalopram, and venlafaxine prevented relapse.[24,74,76]

NONPHARMACOLOGIC THERAPY

Patients should be educated about SAD and support groups. Self-help group programs that focus on effective communication can benefit people with public-speaking phobia.

CBT consists of exposure therapy, cognitive restructuring, relaxation training techniques, and social skills training.[24] Through CBT, patients learn to overcome anxiety in social situations and alter the beliefs and responses that maintain this anxiety. Therapy usually lasts several months and often is conducted in groups. In clinical trials, one-half to two-thirds of patients responded at 12 weeks.[24]

PHARMACOLOGIC THERAPY

Special Populations

SAD can present in children of preschool to elementary school age. If the disorder is not treated, it can persist into adulthood and increase the risk of depression and substance abuse. CBT and social skills training are effective nonpharmacologic therapies in children.[68,77] Placebo-controlled and open-label trials have provided evidence of efficacy of pharmacotherapy with an SSRI or SNRI in children 6 to 17 years of age.[68,77] Children and adolescents prescribed an SSRI or SNRI for social anxiety (or for other purposes) should be closely monitored for increased risk of suicidal ideation. Headache, nausea, drowsiness, insomnia, jitteriness, and stomach aches were reported in children receiving antidepressants.[68,77]

Benzodiazepines should be reserved as the last-line agents in children with SAD.[68,77] If prescribed, they should be used for the shortest time period possible. The adverse effects of benzodiazepines in children include drowsiness, oppositional behavior, disinhibition, and fatigue.

Approximately one-fifth of patients with SAD also suffer from an alcohol use disorder. Many people with SAD report that they use alcohol to cope with anxiety. Paroxetine significantly reduced social anxiety and the frequency and severity of alcohol use in patients with SAD and an alcohol use disorder.[78] MAOIs and benzodiazepines are not appropriate for patients with SAD and alcohol use disorder. SSRIs are the drugs of choice.

Antidepressant Therapy

8 SSRIs and venlafaxine are beneficial for concurrent depression, and are safe when used in patients with substance abuse. Paroxetine, sertraline, extended-release venlafaxine, and extended-release fluvoxamine are approved for the treatment of generalized SAD, and are considered first-line agents because of efficacy and tolerability (Table 79–8). Controlled trials comparing different

TABLE 79-8 Drugs Used in the Treatment of Generalized Social Anxiety Disorder

Class/Generic Name	Brand Name	Starting Dose	Dosage Range (mg/day)
Selective serotonin reuptake inhibitors			
Citalopram[a]	Celexa	20 mg/day	20–40[b]
Escitalopram	Lexapro	5 mg/day	10–20[b]
Fuvoxamine CR	Luvox CR	100 mg	100-300[c]
Paroxetine[a]	Paxil	10 mg/day	10–60[c]
Paroxetine CR	Paxil CR	12.5 mg/day	12.5–37.5[c]
Sertraline[a]	Zoloft	25–50 mg/day	50–200[c]
Serotonin-norepinephrine reuptake inhibitor			
Venlafaxine XR[a]	Effexor XR	75 mg/day	75–225[c]
Monoamine oxidase inhibitor			
Phenelzine	Nardil	15 mg at bedtime	60–90[b]
Alternative agents			
Buspirone[a,d]	BuSpar	10 mg twice per day	45–60[b]
Clonazepam[a,d]	Klonopin	0.25 mg/day	1–4[b]
Gabapentin[a]	Neurontin	100 mg 3 times a day	900–3,600[b]
Mirtazapine[a]	Remeron	15 mg at bedtime	30[b]
Pregabalin	Lyrica	100 mg 3 times a day	600[b]
Quetiapine	Seroquel	25 mg at bedtime	25–400[b]

XR, extended-release; CR, controlled-release.

[c]Dosage is FDA approved.
[d]Used as augmenting agent.
Data from Bandelow et al.,[3] Muller et al.,[17] Schneier,[24] Stein and Stein,[74] and Vaishnavi et al.[80]

SSRIs, or SSRIs and an SNRI, demonstrated equivalent efficacy between agents.[24,79] TCAs are not effective in SAD.[24] Evidence-based guidelines for the treatment of SAD were published by the World Federation of Societies of Biological Psychiatry, the British Association for Psychopharmacology, and the Canadian Psychiatric Association.[3,21,63] An algorithm for the pharmacotherapy of generalized SAD appears in Figure 79–3.

Selective Serotonin Reuptake Inhibitors

Efficacy The efficacy and safety of SSRIs in the treatment of SAD were established in large placebo-controlled trials.[81] Response rates to SSRIs ranged from 50% to 80%.[81]

Patients treated with paroxetine, sertraline, escitalopram, and fluvoxamine showed improvement in anxiety and avoidance symptoms and a decrease in disability.[24,79] SSRIs were well tolerated, and emergent adverse effects were similar to those of depression trials. The onset of effect was delayed 4 to 8 weeks, and maximum benefit was often not observed until 12 weeks or longer. Sertraline was effective in disabled patients suffering from the marked to severe form of generalized SAD.[81] Escitalopram was effective in the treatment of generalized social anxiety.[21,79] Limited data suggest that citalopram is also effective in treating SAD.[82] Mixed results have been reported for fluoxetine.[83]

Dosing and Administration SSRIs should be initiated at doses similar to those used for the treatment of depression and administered as a single daily dose (see Table 79–8). If the patient suffers from comorbid panic disorder, the SSRI dose should be started at one-fourth or one-half of the dose. After 24 weeks of therapy, measures of social anxiety were significantly better with escitalopram 20 mg compared with paroxetine 20 mg.[84] The dose response curve for SSRIs tends to be relatively flat, but individual patients can require higher doses. Increase the dose as tolerated in patients who have not responded after 4 weeks of therapy.[17,24] When discontinuing an SSRI, the dosage should be tapered monthly (i.e., decreasing sertraline by 50 mg or paroxetine by 10 mg) to reduce the risk of relapse and discontinuation symptoms. Escitalopram produced significantly fewer discontinuation symptoms compared with paroxetine in patients with SAD.[21]

Venlafaxine

Efficacy Extended-release venlafaxine was significantly better than placebo in improving social interaction, performance, avoidance factors, and some fear factors (e.g., public speaking).[85] Beneficial effects were seen by week 3. Venlafaxine was effective in patients who failed to respond to therapy with SSRIs.[17]

Adverse Effects Adverse effects included anorexia, dry mouth, nausea, insomnia, and sexual dysfunction.

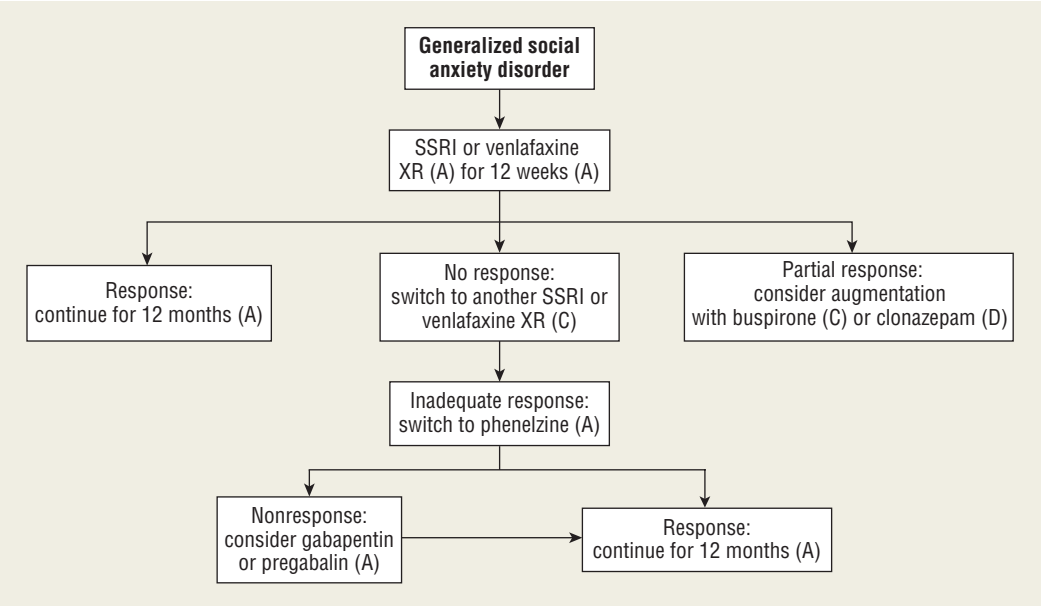

FIGURE 79-3. Algorithm for the pharmacotherapy of generalized social anxiety disorder. Strength of recommendations: A = directly based on category I evidence (i.e., meta-analysis of randomized controlled trials [RCT] or at least one RCT); B = directly based on category II evidence (i.e., at least one controlled study without randomization or one other type of quasi-experimental study); C = directly based on category III evidence (i.e., nonexperimental descriptive studies); D = directly based on category IV evidence (i.e.,expert committee reports or opinions and/or clinical experience of respected authorities). (SSRI, selective serotonin reuptake inhibitor.) *(Data from Bandelow et al.,[3] and Stein and Stein.[74])*

Dosing and Administration Additional therapeutic benefits of venlafaxine above 75 mg/day were not shown.[85] Venlafaxine should be tapered slowly (i.e., decreasing by 37.5 mg/mo) to decrease the risk of relapse during discontinuation.

Mirtazapine Mirtazapine reduced social anxiety and improved QOL in women with SAD over 10 weeks.[86]

Alternative Agents

Benzodiazepines Benzodiazepines are commonly used in the treatment of patients who cannot tolerate or fail to respond to antidepressants.[24] Benzodiazepines are not considered first-line therapy for SAD because of concerns over the adverse effects, potential for dependence, the possibility of rebound anxiety, and ineffectiveness in the treatment of depression.[23,83] Clonazepam is the most extensively studied benzodiazepine for the treatment of generalized SAD.[24] Clonazepam improved fear and phobic avoidance, interpersonal sensitivity, fears of negative evaluation, and disability measures.[87] Adverse effects included sexual dysfunction, unsteadiness, dizziness, and poor concentration.[87]

If clonazepam is prescribed, the acute phase of therapy is about 1 month. Patients should be instructed not to decrease or discontinue clonazepam without consulting their clinician because of the risks of rebound anxiety and withdrawal symptoms. Patients on clonazepam for 6 months who were slowly tapered over 5 months maintained their treatment response.[17,24] Clonazepam should be gradually tapered at a rate not to exceed 0.25 mg every 2 weeks.[17,24]

CLINICAL CONTROVERSY

The role of benzodiazepines in the treatment of SAD is controversial. Some clinicians prescribe benzodiazepines in combination with an antidepressant in the acute management of SAD, then taper the benzodiazepine after 3 to 4 weeks. Recent data indicate that the addition of a benzodiazepine to an SSRI during the acute treatment of SAD does not provide more rapid response, although patients tended to have better outcomes at the end of the trial.

Anticonvulsants Anticonvulsants are another therapeutic option in SAD. Gabapentin, a nonbenzodiazepine GABA analog, was effective for SAD in a 14-week placebo-controlled trial.[17,24] The onset of effect occurred within 2 to 4 weeks. Pregabalin was superior to placebo in an 11-week, placebo-controlled trial and the effective dose was 600 mg/day.[88]

***β*-Blockers** *β*-Blockers decrease the perception of anxiety by blunting the peripheral autonomic symptoms of arousal (e.g., rapid heart rate, sweating, blushing, and tremor), and they are often used to decrease anxiety in performance-related situations. For patients with specific SAD, 10 to 80 mg of propranolol or 25 to 100 mg of atenolol can be taken one hour before a performance as needed.[17,24] A test dose should be taken at home before the presentation to assure that *β*-blockade is sufficient and there are no adverse events. Controlled trials with *β*-blockers do not support daily use in generalized SAD.[17]

Treatment Resistance ❾ An adequate antidepressant trial usually consists of 8 to 12 weeks (at maximum dosages).[17,24] Subsequent options include a trial of a second SSRI or extended-release venlafaxine. Some patients experience clinical benefit during the first 4 weeks of therapy.[21,72] If nonresponsiveness continues, a trial of an alternative agent is warranted.

There are no data on the choice of treatments if antidepressants fail. Busprione[24,72] and clonazepam (in patients without a history of substance abuse) have been used as augmenting agents.[21] The combination of clonazepam and paroxetine over 10 weeks in a placebo-controlled trial did not lead to more rapid resolution of SAD symptoms.[87] However, the group that received the combination therapy had a higher response rate.

Atypical antipsychotics and MAOIs are options in treatment-resistant SAD. Quetiapine monotherapy showed a large effect size on the Social Phobia Inventory when compared with placebo.[80] Although phenelzine is effective in 77% of patients with SAD,[21,73] dietary restrictions, potential drug interactions, and adverse effects (e.g., weight gain and hypertensive crisis) have limited its use. If a patient is switched from another antidepressant to phenelzine, an appropriate washout period should be followed.

PHARMACOECONOMIC CONSIDERATIONS

Generalized SAD is associated with lower health-related QOL, a higher rate of lifetime suicide attempts, diminished educational and occupational attainment, and increased use of healthcare resources.[83] SAD was a significant, unrecognized impediment to efforts to reduce welfare reliance and achievement of economic self-sufficiency in women receiving welfare.[89]

Early intervention is important in the treatment of SAD. Patients treated with fluvoxamine, sertraline, paroxetine, or escitalopram showed a significantly greater improvement in functioning, disability, and QOL compared with placebo-treated patients.[24,80,90,91] In a relapse prevention study, patients treated with escitalopram experienced a better health-related QOL and more cost-effective therapy than placebo.[91] The acquisition cost of escitalopram was more than offset by a decrease in total costs of care.[91]

EVALUATION OF THERAPEUTIC OUTCOMES

❿ The pharmacotherapy of SAD can be monitored in three principal domains: SAD symptoms (e.g., fears and physical symptoms), functionality, and well-being or overall improvement.[17,24] Response to pharmacotherapy in SAD is defined as a stable, clinically meaningful improvement; patients no longer have the full range of symptoms but typically continue to experience more than minimal symptoms.[17,24]

During the acute phase of treatment, patients should be seen weekly while the drug dosage is titrated. Once the patient responds and the dosage is stabilized, the patient can be seen monthly. Many patients report improvement during the first 4 weeks of therapy, but more than a quarter of those who do not have a response at week 8 may have a response at 12 weeks. At each visit, the patient should be asked about adverse effects and improvement in symptoms. The patient should be instructed to keep a diary to record fear levels, physical symptoms, cognitions, and anxious behaviors in actual exposures to social situations. The Liebowitz Social Anxiety Scale is a clinician-rated scale of clinical severity and change in SAD for monitoring response.[17,24] Patients can use the Social Phobia Inventory for self-assessment of SAD symptoms.[24] Full remission is a complete resolution of symptoms across the three SAD domains that is maintained for 3 months or a Liebowitz Social Anxiety Scale score of less than or equal to 30 points.[71]

Patient counseling is important. Patients should be instructed about the gradual onset of effect, when to expect full therapeutic effects, and that long-term therapy is required. When drug therapy is discontinued, the dosage needs to be gradually decreased over several months, and the patient should be seen more frequently to monitor for signs and symptoms of relapse or withdrawal.

It is important to remember that although pharmacotherapy usually leads to improvement in social and occupational functioning, most patients do not achieve a full remission. Many patients require additional treatment, often in the form of CBT.

TREATMENT

Specific Phobia

Specific phobia is considered unresponsive to drug therapy, although highly responsive to CBT. The use of benzodiazepines or paroxetine in patients who failed CBT is supported by limited data. Benzodiazepines can be detrimental in patients with specific phobias treated with CBT.[21]

CONCLUSIONS

Anxiety disorders are common in the population and occur concurrently with other psychiatric disorders. The proper management of anxiety disorders begins with the correct diagnosis; not all patients should receive antianxiety agents. Nonpharmacologic interventions often are effective alone or when combined with drug therapy.

There are several subtypes of anxiety disorders, and the diagnosis determines the type of drug and nonpharmacologic intervention selected. Although benzodiazepines remain the drugs of choice for situational anxiety, antidepressants have emerged as first-line therapy for GAD, panic disorder, and SAD. Benzodiazepines are reserved for use in situations requiring immediate anxiety relief during the first 2 to 4 weeks of therapy with a long-term agent such as an antidepressant. Antidepressants, including SSRIs and SNRIs, and the benzodiazepines clonazepam and alprazolam, are used extensively in patients with GAD, panic disorder, and SAD.

The long-term goal of therapy for GAD, panic disorder, and SAD is remission of core anxiety symptoms with no impairment in functionality, minimal anxiety, and no depressive symptoms. Augmentation with atypical antipsychotics show some promise in treatment-resistant cases.

ABBREVIATIONS

ACC: anterior cingulated cortex

CBT: cognitive behavioral therapy

CNS: central nervous system

CRF: corticotrophin-releasing factor

DA: dopamine

DMDZ: desmethyldiazepam

GABA: γ-aminobutyric acid

GAD: generalized anxiety disorder

FDA: U.S. Food and Drug Administration

5-HT: serotonin

LC: locus ceruleus

MAOI: monoamine oxidase inhibitor

NE: norepinephrine

OCD: obsessive-compulsive disorder

PAG: periaqueductal gray matter

PTSD: posttraumatic stress disorder

QOL: quality of life

SAD: social anxiety disorder

SERT: serotonin reuptake transporter site

SNRI: serotonin-norepinephrine reuptake inhibitor

SSRI: selective serotonin reuptake inhibitor

TCA: tricyclic antidepressant

CHAPTER 80

Anxiety Disorders II: Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder

CYNTHIA K. KIRKWOOD, LISA B. PHIPPS, AND BARBARA G. WELLS

KEY CONCEPTS

1. The short-term goal in posttraumatic stress disorder (PTSD) is reduction in core symptoms, while the long-term goal is remission.
2. Cognitive behavioral therapy and eye movement desensitization and reprocessing are the most effective nonpharmacologic methods to reduce symptoms of PTSD.
3. The selective serotonin reuptake inhibitors or venlafaxine are considered first-line treatment for PTSD.
4. An adequate trial of selective serotonin reuptake inhibitors (SSRIs) in PTSD requires appropriate dosing, titration, and duration of treatment.
5. PTSD compares with depression in the level of disability it imposes on patients.
6. SSRIs are the drugs of choice for the treatment of obsessive-compulsive disorder (OCD).
7. If an inadequate response to an SSRI for OCD occurs after 4 to 6 weeks at the maximum dose, switch to another SSRI.
8. Medication taper can be considered after 1 to 2 years of treatment in patients with OCD.

Current world and local events (e.g., wars, terrorist attacks, earthquakes, kidnappings, interpersonal violence) have placed a renewed focus on posttraumatic stress disorder (PTSD). Initially diagnosed in veterans of war, PTSD is now acknowledged as a significant psychiatric illness in the civilian population and more recently among deployed service personnel of the Afghanistan and Iraq campaigns.[1,2] PTSD continues to be poorly recognized and diagnosed in clinical practice.[3] Because of its co-occurrence with other anxiety disorders, depression, and substance abuse, the overlapping symptoms can lead to diagnostic uncertainty. Advances in the science and treatment of PTSD can assist clinicians in all fields of healthcare to screen patients for a history of trauma and effectively manage PTSD if it is present.

Intrusive obsessive thoughts and compulsive ritualistic behaviors characterize obsessive-compulsive disorder (OCD). OCD can be severely debilitating and impair functioning in social, family, and work settings, with an overall decrease in quality of life (QOL).[4] OCD is associated with an increased risk of suicide, with 27% of patients reporting a previous history of suicide attempt.[5] Increased understanding of symptom dimensions and treatment response can improve QOL in patients suffering from OCD.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

The estimated lifetime prevalence of PTSD is 6.8% in the U.S. population.[6] Lifetime prevalence of OCD has been estimated at 1.6% in the general population and 2% to 4% in the pediatric population.[6,7]

PTSD is associated with the incidence of trauma. It is estimated that approximately 50% of men and 60% of women are exposed to a life-threatening traumatic event. Of these individuals 8.2% of men and 20% of women will develop PTSD.[8] Previous exposure to a trauma and the intensity of response to the event increase the risk of PTSD.[8] Men tend to be assaulted more frequently, but women have a higher rate of PTSD after assault. The incidence of PTSD is equal between men and women after rape (i.e., 50%) and natural disasters (i.e., less than 5%).[8] Genetic factors can increase vulnerability to PTSD if an individual is exposed to a traumatic event. Offspring of Holocaust survivors had a higher lifetime prevalence rate of PTSD compared with a control group.[8]

The epidemiology of OCD is influenced by age and gender. OCD typically begins early in life, with 20% of cases occurring in childhood, 29% in adolescence, and 49% of cases occurring by age 20.[1] Age of onset has a bimodal distribution with peaks around 10 and 21 years.[7] The onset of illness is earlier in men than in women.[1] Higher rates of other anxiety disorders are reported in first-degree relatives of patients with OCD.[9] Early age of onset has been associated with higher probabilities of comorbid impulse-control, somatoform, eating, and tic disorders.[10] Heredity is stronger when there is an early age of onset or comorbidity with tic disorders.[11]

ETIOLOGY

The exact etiologies of PTSD and OCD are not known. It is likely that abnormalities in several areas of brain functioning interact to cause these chronic anxiety disorders. Genetics may play a role in expression of PTSD and OCD, but environmental factors likely are also involved.

OCD has been characterized as a pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections (PANDAS). In response to streptococcal infection, antibodies are produced in some individuals that temporally precipitate sudden onset or exacerbation of symptoms of OCD. Neuroimaging studies suggest that in these patients the antibodies produce inflammation of the basal ganglia. This leads to increased volumes of the caudate, putamen,

and the globus pallidus, and subsequently to smaller caudate volumes potentially reflective of scarring or atrophy related to streptococcal infection.[12] Although most patients with OCD do not have a streptococcal etiology, an accurate medical history regarding onset of illness is imperative because specific treatment strategies are indicated.

PATHOPHYSIOLOGY

Research findings in the areas of neuroendocrinology, neurobiology, and neuroimaging have advanced a number of theories on the pathophysiology of anxiety disorders. Neuroendocrine changes in the hypothalamic-pituitary-adrenal (HPA) axis are implicated in the pathophysiology of PTSD.[8] As reviewed in the previous chapter (Chapter 79), data from neurochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain (e.g., amygdala, hippocampus, thalamus, and prefrontal cortex).[8,13] Abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ-aminobutyric acid (GABA), glutamate, dopamine (DA), and serotonin (5-HT) may affect the manifestations of anxiety disorders.[8,14]

NEUROENDOCRINE THEORIES

Neuroendocrine studies provide data that abnormalities occurring pretrauma, during trauma, and posttrauma contribute to PTSD.[8] Normally the immediate reaction to stress occurs as an automatic response from the amygdala to the sympathetic and parasympathetic systems and the HPA axis. The release of corticotropin-releasing factor (CRF) stimulates cortisol secretion from the adrenal gland. Both catecholamines and cortisol levels rise in tandem. Cortisol reduces the stress response by tempering the sympathetic reaction through negative feedback on the pituitary and hypothalamus.[8] These systems return to normal after a few hours.

Recent data implicate a role for the neuropeptides CRF and neuropeptide Y (NPY) in PTSD. Patients with PTSD have a hypersecretion of CRF but demonstrate subnormal levels of cortisol at the time of trauma and chronically.[8] Lower plasma cortisol concentrations were associated with greater severity of PTSD symptoms in nonmilitary patients.[14] Dysregulation of the HPA axis is postulated to be a risk factor for eventual development of PTSD.[8] Higher plasma concentrations of NPY were found in combat-exposed men who did not develop PTSD and could play a role in resiliency.[14]

NEUROCHEMICAL THEORIES

Several neurotransmitters may be involved in the pathophysiology of PTSD. 5-HT, NE, and glutamate are associated with the processing of emotional and somatic contents of memories in the amygdala. The cortex and hippocampus are involved in storing the facts and related cues of memory.[14] The noradrenergic theory posits that the autonomic nervous system of anxious patients is hypersensitive and overreacts to stimuli. The alarm center, the locus ceruleus, releases NE to stimulate the sympathetic and parasympathetic nervous systems. Hyperactive noradrenergic signaling in patients with PTSD is a consistent research finding and includes increased 24-hour catecholamine excretion.[14] Glutamate signaling abnormalities may result in distortion of amgydala-dependent emotional processing under stress.[14] Dysregulation of the processing of sensory input and memories may contribute to the dissociative and hypervigilant symptoms in PTSD. Abnormalities of GABA inhibition may lead to increased awareness or response to stress, as seen in PTSD.[14]

Both 5-HT and DA are implicated in the pathogenesis of OCD. Selective and potent serotonergic reuptake inhibitors have consistently been shown effective for symptoms of the illness.[15–18] A recent meta-analysis concluded that higher doses of selective serotonin reuptake inhibitors (SSRIs) were associated with improved efficacy in the treatment of OCD.[18] A Cochrane systematic review of 17 studies found that SSRIs were more effective than placebo in treating symptoms of OCD, and that SSRIs were similar to each other in efficacy.[17] DA dysregulation may contribute to some forms of OCD. Neurologic symptoms (e.g., tics) are part of the clinical presentation in some patients with OCD. Tourette's disorder, a disorder of DA function, is often a concurrent disease.[1] Augmentation with antipsychotic drugs may improve symptoms in patients with OCD who are partially or nonresponsive to SSRI monotherapy.[19–21]

NEUROIMAGING STUDIES

Neuroimaging studies suggest that certain areas of the brain are altered by psychologic trauma. In PTSD most functional neuroimaging studies have involved the amygdala, ventromedial prefrontal cortex (vmPFC), and hippocampus. Findings of increased activation of the amygdala after trauma-related imagery, sounds, or smells indicate that this structure plays a role in the persistence of traumatic memory.[13] Decreased amygdala activation is correlated with resilience to PTSD and response to cognitive behavioral therapy (CBT).[13] Hypofunctioning of the vmPFC is theorized to prevent extinction in patients with PTSD and is inversely correlated with severity of symptoms.[13,22] The most consistent findings are decreased hippocampal volumes and *N*-acetylaspartate levels in patients with PTSD.[13,22] In twin studies, the unaffected twin of patients with PTSD also demonstrated smaller hippocampi compared with twins without PTSD.[22] These findings suggest that lower hippocampal volumes in patients with PTSD are likely a precursor associated with vulnerability for subsequent development of PTSD.[23]

Neuroimaging studies of two models suggest that dysfunction in the cortical-striatal-thalamic circuits is responsible for impulsive behavior and inability to regulate socially acceptable behaviors.[24] Drugs that decrease hyperactivity in the cortical-striatal-thalamic circuits are theorized to decrease symptoms of OCD.[25]

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* classifies anxiety disorders into several categories: generalized anxiety disorder, panic disorder (with or without agoraphobia), social anxiety disorder, specific phobia, OCD, PTSD, and acute stress disorder (ASD).[1] The characteristic features of these illnesses are anxiety and avoidance behavior. Generalized anxiety disorder, panic disorder, and social anxiety disorder are discussed in Chapter 79.

CLINICAL PRESENTATION OF POSTTRAUMATIC STRESS DISORDER

Re-Experiencing Symptoms

- Recurrent, intrusive distressing memories of the trauma
- Recurrent, disturbing dreams of the event
- Feeling that the traumatic event is recurring (e.g., dissociative flashbacks)
- Physiologic reaction to reminders of the trauma

Avoidance Symptoms

- Avoidance of conversations about the trauma
- Avoidance of thoughts or feelings about the trauma
- Avoidance of activities that are reminders of the event

- Avoidance of people or places that arouse recollections of the trauma
- Inability to recall an important aspect of the trauma
- Anhedonia
- Estrangement from others
- Restricted affect
- Sense of a foreshortened future (e.g., does not expect to have a career, marriage)

Hyperarousal Symptoms

- Decreased concentration
- Easily startled
- Hypervigilance
- Insomnia
- Irritability or anger outbrusts

Subtypes

- Acute: duration of symptoms is less than 3 months
- Chronic: symptoms last for longer than 3 months
- With delayed onset: onset of symptoms is at least 6 months posttrauma

Data from American Psychiatric Association[1] and Ballenger et al.[23]

POSTTRAUMATIC STRESS DISORDER

Exposure to a traumatic event is required for a diagnosis of PTSD.[1] The person must have witnessed, experienced, or have been confronted with a situation that involved definite or threatened death or serious injury, or possible harm to themselves or others. The patient's response to the trauma must include intense fear, helplessness, or horror.[1] Some examples of traumatic events include physical attacks by an intimate partner, road traffic accidents, military combat exposure, natural disasters, being held hostage, child sexual abuse, and witnessing a murder or injury of another.

The resulting PTSD symptoms include persistent reexperiencing of the traumatic event, avoidance of stimuli associated with the trauma, numbing of general responsiveness, and persistent symptoms of hyperarousal. Patients must have at least one reexperiencing symptom, at least three signs or symptoms of persistent avoidance of stimuli associated with the trauma, and at least two symptoms of increased arousal.[1] Symptoms from each category need to be present for longer than 1 month and cause significant distress or impairment in functioning. Most persons diagnosed with PTSD also meet criteria for another mental disorder.[1]

Anxiety and dissociative symptoms (e.g., sense of numbing or absence of emotional responsiveness, derealization, depersonalization, inability to recall important features of the event) emerging within 1 month after exposure to a traumatic stressor are classified as ASD. Symptoms of ASD are experienced during or immediately after the trauma, last for at least 2 days, and resolve within 4 weeks.[1]

The age of onset and course of PTSD are variable. PTSD can occur at any age. The presentation is not predictable because symptoms are related to the duration and intensity of the trauma, the presence of other psychiatric disorders, and how the patient deals with the trauma. Symptoms emerge soon after a traumatic event and either dissipate or chronically persist in survivors.[26] About 95% of patients who recover do so within a year, and 40% have persistent symptoms 6 years later. PTSD co-occurs with mood, anxiety, and substance use disorders. The course of illness is fluctuating, worsening with life stressors.[26]

OBSESSIVE-COMPULSIVE DISORDER

CLINICAL PRESENTATION OF OBSESSIVE-COMPULSIVE DISORDER

Obsessions

- Repetitive thoughts (e.g., feeling contaminated after touching an object, doubting whether the stove was turned off)
- Repetitive images (e.g., recurrent sexually explicit pictures)
- Repetitive impulses (e.g., need for symmetry or putting things in specific order, impulse to shout out obscenities in a church)

Compulsions

- Repetitive activities (e.g., hand washing, checking, ordering, need to ask, need to confess)
- Repetitive mental acts (e.g., counting, repeating words silently, praying)

Data from American Psychiatric Association[1] and Jenike.[27]

Patients with OCD exhibit a great variety of symptoms on presentation to clinicians. The diversity and oddity of symptoms that manifest can obscure accurate diagnosis and delay appropriate treatment of the disorder. Patients can be secretive about symptoms and purposefully refuse to report symptoms.[27] Patients can present in a seemingly incongruous manner to nonpsychiatrists for other complaints—dermatologists for eczema or chapped skin, pediatricians for parental concerns over a child's compulsive hand washing, neurologists for tics, or dentists for gum lesions from compulsive teeth brushing.

The diagnostic criteria for OCD requires the presence of obsessions and/or compulsions (although most patients have both) that are severe enough to cause marked distress, to be time-consuming (occupy more than 1 hour per day), or to cause significant impairment in social or occupational functioning.[1] An obsession is a recurrent, persistent idea, thought, impulse, or image that is experienced as intrusive and inappropriate and produces marked anxiety. Common obsessions involve thoughts about contamination (e.g., concern with germs or dirt), repeated doubts, and needing to have things in a particular order.[1]

Individuals must recognize that their obsessions or compulsions are excessive or unreasonable. Obsessions must be acknowledged as products of the individual's own mind, and attempts must be made to ignore or suppress them. The obsessions produce marked feelings of anxiety and are not simply excessive worry about a real-life situation.[1]

A compulsion is defined as a repetitive behavior or mental act generally performed in response to an obsession. The most common compulsions involve washing and cleaning, counting, checking, and requesting or demanding assurances. Diagnostically, compulsive behavior is not pleasurable and is designed to prevent discomfort or the occurrence of a dreaded event that is often unknown. For example, many patients are obsessed with feelings of doubt (e.g., whether a door was left unlocked), causing them marked distress and leading to repetitive checking (or compulsive behaviors). These behaviors are usually performed according to certain rules or in a stereotyped fashion. Because patients recognize their compulsive behavior as silly or senseless, they become extremely adept at denying symptoms, disguising their rituals, and concealing their illness from friends and family.[1]

Patients with OCD often have concurrent depression, anxiety disorders, and alcohol abuse or dependence.[27] It is a chronic illness in most patients, with severity of symptoms varying in intensity over time. Many patients with OCD have significantly impaired QOL and ability to function. Irritable bowel syndrome has been associated with OCD, with one study reporting that approximately

35% of patients with OCD met criteria for irritable bowel syndrome compared with 2.5% of a control group.[28]

TREATMENT

Posttraumatic Stress Disorder

DESIRED OUTCOME

1 The short-term goal of therapy in the management of PTSD is reduction in core symptoms (i.e., intrusive reexperiencing, avoidance, and hyperarousal). Patients should also have improvements in disability, concurrent psychiatric conditions, and QOL. The long-term goal in PTSD is remission.[29]

GENERAL APPROACH TO TREATMENT

In general, patients who seek treatment acutely after a trauma and are in intense distress should receive therapy based on their presenting symptoms (e.g., a nonbenzodiazepine hypnotic for difficulty sleeping). Short courses of trauma-focused cognitive behavioral therapy (TFCBT) can be helpful to prevent chronic PTSD in patients who present during the first 3 months of the event.[23] If symptoms (e.g., hyperarousal, avoidance, dissociation, sleep difficulties, or depressed mood) persist for 3 to 4 weeks and the patient experiences marked social, occupational, and/or interpersonal impairment, they can be treated with pharmacotherapy, psychotherapy, or both. Many patients with PTSD will improve substantially with pharmacotherapy but retain some symptoms. Treatment regimens usually combine psychoeducation, psychosocial support and/or treatment, and pharmacotherapy.[23]

NONPHARMACOLOGIC THERAPY

Psychotherapy can be used when a patient suffers from mild symptoms, in patients who prefer not to use medications, or in conjunction with drugs in patients with severe symptoms to improve response.[23] Patients who have experienced trauma should be educated that they can experience anxiety, depression, nightmares, and even flashbacks as a normal reaction to the event.[23] Brief courses of CBT in close proximity to the traumatic event resulted in lower rates of PTSD 3 and 6 months later.[23] Single-session critical incident stress debriefing was not shown to be effective in preventing development of PTSD and actually can cause harm.[23]

2 Psychotherapies for treating PTSD include stress management, TFCBT and eye movement desensitization and reprocessing (EMDR), and psychoeducation.[30] Short-term reductions in symptoms can be achieved with stress management, group therapy, hypnosis, or psychodynamic therapy.[30] Cognitive and behavioral approaches are more effective than stress management or group therapy to reduce symptoms of PTSD.[31] Either TFCBT or EMDR can be used if symptoms are evident for longer than 3 months postevent.[32] Followup studies after a 3-month course of CBT demonstrated continued benefit for 3 to 12 months.[31] An 8-week comparison found EMDR more successful in maintaining improvements in PTSD scores than fluoxetine or placebo.[33] Psychoeducation includes information about the disease state, treatment options, and avoidance of excessive use of alcohol, nicotine, and other substances of abuse.

PHARMACOLOGIC THERAPY

3 Antidepressants are the major pharmacotherapeutic treatment for PTSD. In addition to their efficacy in PTSD, these agents are also effective for concurrent depression and anxiety disorders. SSRIs[34] or venlafaxine are the first-line pharmacotherapy of PTSD.[29] The tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) can also be effective, but they have less favorable side-effect profiles (Table 80–1). Sertraline and paroxetine are both approved for the acute treatment of PTSD,[35,36] and sertraline is approved for the long-term (i.e., 52 weeks) management of PTSD.[36] A number of drugs can be used as augmentation agents (e.g., antiadrenergic drugs and atypical antipsychotics).[29] Benzodiazepines are not effective for PTSD.[23,29] A number of treatment guidelines are published (see Stein et al., 2009 for review).[37] An algorithm from the International Psychopharmacology Algorithm Project for the treatment of PTSD appears in Figure 80–1.

TABLE 80-1 Antidepressants Used in the Treatment of Posttraumatic Stress Disorder

Class/Generic Name	Starting Dose	Dosage Range (mg/day)
Selective serotonin reuptake inhibitors		
Citalopram[a]	20 mg/day	20–60[b]
Escitalopram	5 or 10 mg/day	10–20[b]
Fluoxetine[a]	10 mg/day	10–60[b]
Fluvoxamine[a]	50 mg/day	100–300[b]
Paroxetine[a]	10–20 mg/day	20–50[c]
Sertraline[a]	25 mg/day	50–200[c]
Other agents		
Amitriptyline[a]	25 or 50 mg/day	50–300[b]
Imipramine[a]	25 or 50 mg/day	50–300[b]
Mirtazapine[a]	15 mg/night	15–60[b]
Phenelzine	15 or 30 mg every night	15–90[b]
Venlafaxine extended-release[a]	37.5 mg/day	37.5–300[b]

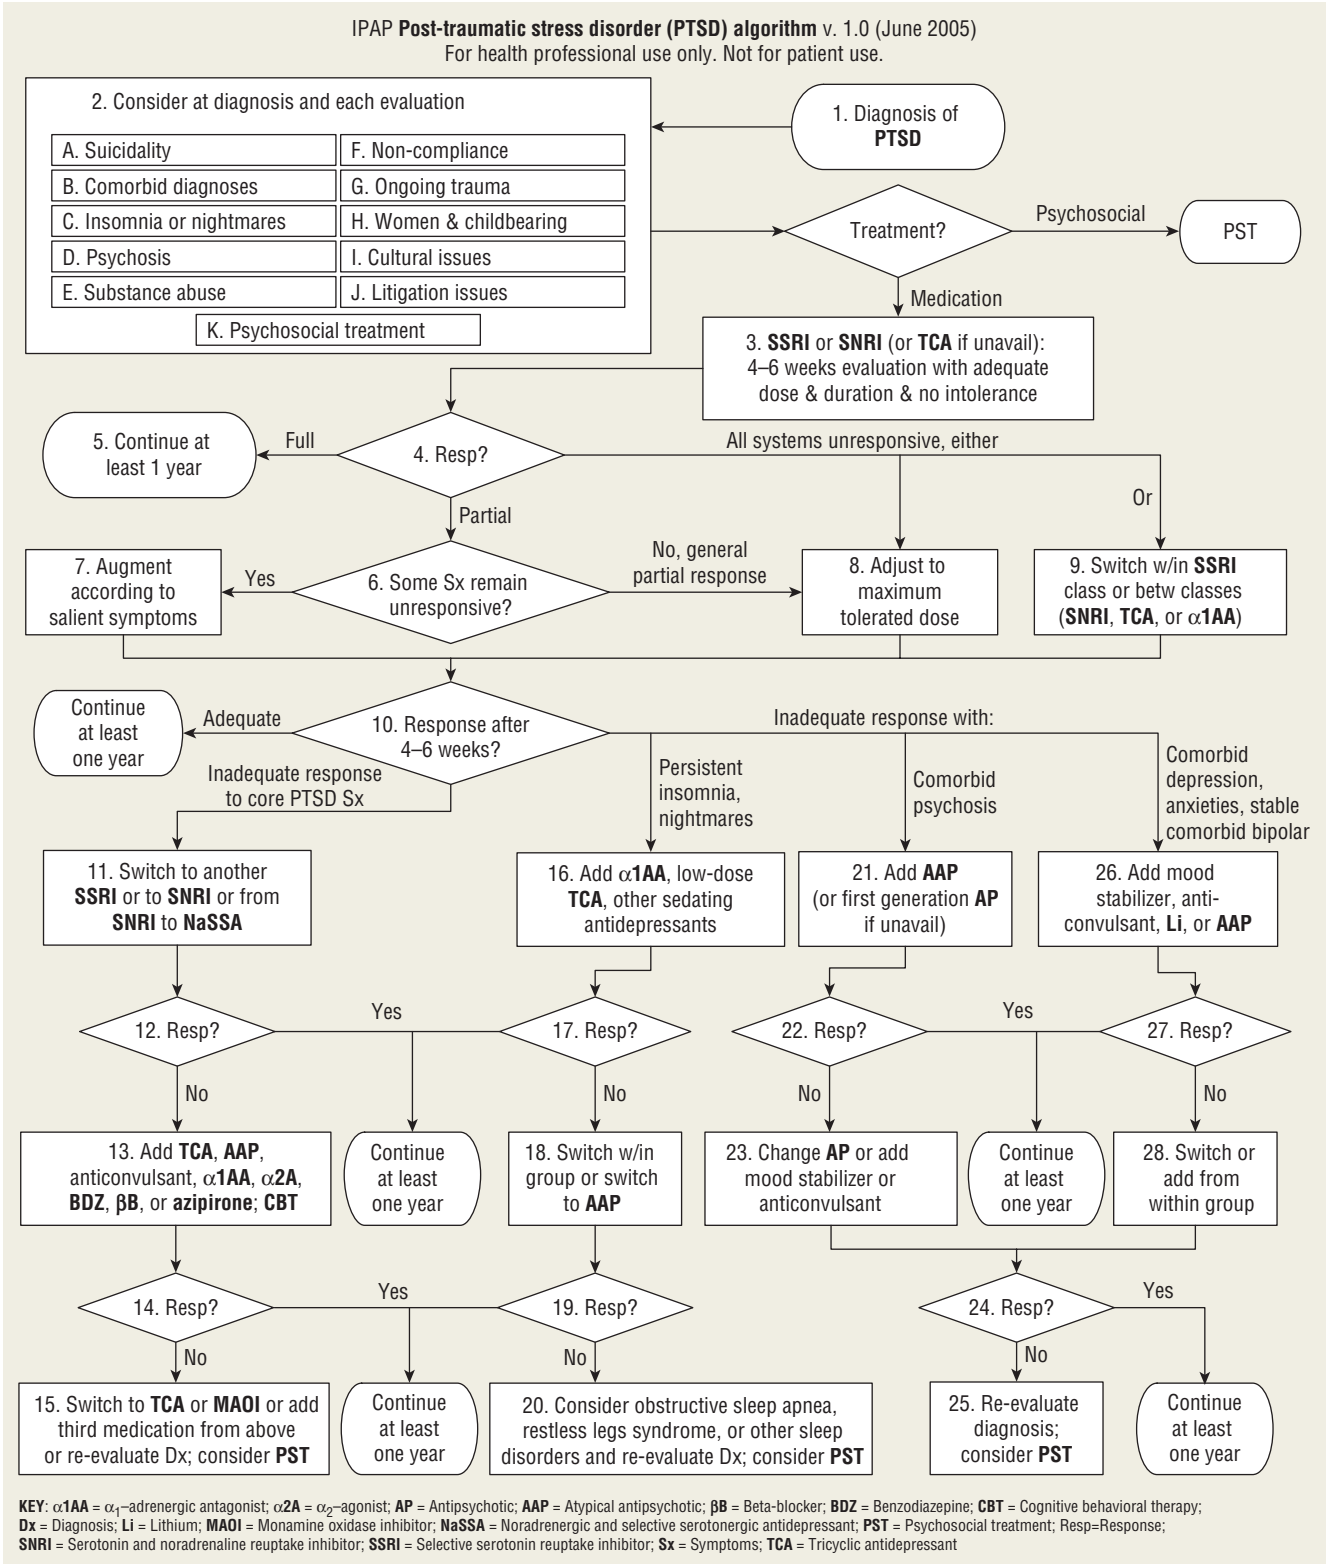
[a]Available generically.
[b]Dosage used in clinical trials but not FDA approved.
[c]Dosage is FDA approved.
Date from Ballenger et al.[23] International Psychopharmacology Algorithm Project,[29] Paxil [package insert],[35] and Zoloft [package insert][36].

Special Populations

Children who experience stress and trauma (e.g., sexual or physical abuse or loss of a parent) are predisposed to develop mood and anxiety disorders. SSRIs are the initial pharmacologic agents of choice in this patient population. Psychotherapy is also a treatment option (e.g., play therapy).[38]

Antidepressant Therapy

Selective Serotonin Reuptake Inhibitors SSRIs act pharmacologically to enhance serotonergic functioning. Large prospective studies documented the efficacy of sertraline and paroxetine in the acute management of PTSD. In a 12-week trial sertraline was effective across the spectrum of PTSD-specific, global, and functional outcome measures. Approximately 60% of the patients improved on symptom clusters of arousal and avoidance/numbing but not on reexperiencing.[39] Sixty percent of patients with PTSD receiving a paroxetine dose of 20 mg/day and 54% of patients receiving 40 mg/day responded; response was not related to dose.[40] In a flexible-dose trial, paroxetine significantly improved all three PTSD symptom clusters and disability compared with placebo at 12 weeks.[41] Fluoxetine showed efficacy in a placebo-controlled trial,[42] and fluvoxamine[43] and escitalopram[44] were efficacious in open trials in acute PTSD. In a comparison between sertraline and citalopram, PTSD symptoms improved significantly in both groups, but sertraline was significantly better in reducing avoidance/numbing than citalopram.[45] In general, SSRIs reduced the numbing symptoms of PTSD, whereas other drugs have not. Adverse reactions reported in patients with PTSD treated with SSRIs include gastrointestinal symptoms, sexual dysfunction, insomnia, and agitation. The results



KEY: **α1AA** = α_1–adrenergic antagonist; **α2A** = α_2–agonist; **AP** = Antipsychotic; **AAP** = Atypical antipsychotic; **βB** = Beta-blocker; **BDZ** = Benzodiazepine; **CBT** = Cognitive behavioral therapy; **Dx** = Diagnosis; **Li** = Lithium; **MAOI** = Monamine oxidase inhibitor; **NaSSA** = Noradrenergic and selective serotonergic antidepressant; **PST** = Psychosocial treatment; Resp=Response; **SNRI** = Serotonin and noradrenaline reuptake inhibitor; **SSRI** = Selective serotonin reuptake inhibitor; **Sx** = Symptoms; **TCA** = Tricyclic antidepressant

FIGURE 80-1. Algorithm for the pharmacotherapy of posttraumatic stress disorder. Levels of evidence (LOE): 1 = more than one adequately powered placebo-controlled trial (i.e., n = 30 per group or greater); 2 = one or more small placebo-controlled trials of monotherapy, combination or augmentation therapy; 3 = case series or open-label trials; 4 = either no published evidence, or presence of clinical consensus. LOE: Node 3 – LOE 1 (sertraline, paroxetine, fluoxetine); LOE 2 (mirtazapine, TCAs, MAOIs); LOE 3 (citalopram); LOE 4 (fluovoxamine); Node 7 – LOE 2 (prazosin, nefazodone, TCAs); LOE 3 (trazodone); Node 9 – LOE 4; Node 13 – Aggression, LOE 2 (prazosin, risperidone, olanzapine), Insomnia/nightmares, LOE 3 (trazodone), Anxiety/agitation, LOE 2 (risperidone), LOE 3 (olanzapine, buspirone), LOE 4 (tiagabine, β-blockers, α_2-agonists); Node 15 – LOE 4; Node 16 – LOE 2, 3 (prazosin); LOE 4 (trazodone, TCAs, olanzapine, mirtazapine, quetiapine, zolpidem); Node 18 – LOE 4; Node 21 – LOE 2 (risperidone), LOE 3 (olanzapine, quetiapine) LOE 4 (SSRIs, anticonvulsants, antiadrenergics); Node 23 – LOE 4; Node 26 – LOE 4; Node 28 – LOE 4 (α1AA, α_1-adrenergic antagonist; α2A, α_2-agonist; AP, antipsychotic; AAP, atypical antipsychotic; βB, beta-blocker; BDZ, benzodiazepine; CBT, cognitive behavioral therapy; Dx, diagnosis; Li, lithium; MAOI, monoamine oxidase inhibitor; NaSSA, noradrenergic and selective serotonergic antidepressant; PST, psychosocial treatment; PTSD, posttraumatic stress disorder; Resp, response; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; Sx, symptoms; TCA, tricyclic antidepressant.) *(Data from International Psychopharmacology Algorithm Project.[29])*

of two long-term trials indicate that sertraline (12 months) and fluoxetine (9 months) were effective in preventing relapse.[45,46]

Other Antidepressants The SNRI venlafaxine has shown efficacy in PTSD. In a 12-week, placebo-controlled trial comparing venlafaxine extended-release and sertraline, venlafaxine was effective in reducing the avoidance/numbing and hyperarousal clusters of PTSD, whereas sertraline improved all PTSD symptom clusters.[47] The remission rates for venlafaxine extended-release were 30.2% after 12 weeks[41] and 50.1% after 6 months.[48]

Other antidepressants have been studied in controlled trials. Mirtazapine was effective on global ratings of symptoms in 64% of patients with PTSD in doses up to 45 mg/day and is considered a second-line agent.[49] Bupropion sustained-release was not effective in patients with chronic PTSD.[50]

The TCAs amitriptyline and imipramine are considered second-line agents and the MAOI phenelzine is considered a third-line antidepressant if therapeutic trials of SSRIs or venlafaxine have failed. Phenelzine decreased insomnia, nightmares, and flashbacks. TCAs are associated with a higher burden of adverse effects compared with SSRIs (e.g., daytime drowsiness, toxicity in overdose, and poor compliance).[29]

Alternative Drug Treatments

Atypical antipsychotics, α_1-adrenergic antagonists, antidepressants, mood stabilizers, anticonvulsants, beta-blockers, and azapirones can be used as augmenting agents for persistent symptoms, in cases of partial response to SSRI therapy after 4–6 weeks, or for comorbidities.[29] Risperidone reduced PTSD symptoms in combat veterans on antidepressants with and without psychosis.[51] Olanzapine added adjunctively to SSRIs decreased PTSD symptoms and significantly improved sleep compared with placebo. Patients gained an average of 13.2 pounds (6 kg) over the course of the 8-week trial.[51] Quetiapine reduced core PTSD symptoms over a 8-week period when added to concurrent therapy.[52]

CLINICAL CONTROVERSY

When a patient with PTSD has a partial response to an SSRI the clinician must choose whether to increase the dose of the SSRI, augment with a second agent, or do both simultaneously. There are no published guidelines to direct clinicians with this therapeutic dilemma.

Prazosin can be useful in some patients with PTSD. Prazosin decreased nightmares and sleep disturbances and improved the core PTSD symptoms in daily doses of 1 to 4 mg. Its presumed mechanism of action is reduction of noradrenergic transmission.[53] Other options for persistent sleep disturbances with less evidence include trazodone, mirtazapine, low dose sedating TCAs, atypical antipsychotics, and zolpidem.[29]

Anticonvulsants, mood stabilizers, buspirone, and beta-blockers can assist in managing aggression.[29]

Dosage and Administration

Acute Phase PTSD symptoms respond slowly to pharmacotherapy, and some patients never experience full resolution. SSRIs should be started 3 to 4 weeks after exposure to a trauma in patients with no improvement in their acute stress response.[23] The initiation of an SSRI should be at a low dose with gradual titration upward toward antidepressant doses. (1) Six to 12 weeks is an appropriate duration of antidepressant therapy to determine response.[29,54]

The dose of sertraline can be increased in weekly intervals by 50 mg/day up to a maximum dosage of 200 mg/day. Paroxetine can be increased by 10 mg/day in weekly intervals to a target dose of 40 mg/day. The dosing of other antidepressants is shown in Table 80–1.

Continuation Phase Many patients are undergoing psychotherapy during the continuation phase of therapy, and dosages can vary as patients deal with past traumatic experiences. During this phase symptoms continue to improve, and the maximal drug benefit (i.e., improvement of disability) accrues.[54] Six-month relapse prevention trials in patients responsive to fluoxetine or sertraline indicate low rates of relapse with SSRI therapy compared with placebo.[54]

Maintenance and Discontinuation Patients with PTSD who respond to pharmacotherapy should continue treatment for at least 12 months.[29,54] If residual symptoms persist, drug therapy should be continued. The decision about when to discontinue therapy is based on response to therapy, presence of ongoing stresses, and adverse effects. The patient must be confident in the discontinuation plan and can require extra support throughout the process. Drug therapy should be withdrawn and tapered slowly over a period of at least 1 month to reduce the potential for relapse.

PHARMACOECONOMIC CONSIDERATIONS

(5) PTSD compares with depression in the level of disability it imposes on patients with the disorder.[55] Individuals fail to realize their potentials for career development, marriage, and education. Women in a healthcare maintenance organization with high scores on the Posttraumatic Stress Disorder Checklist had more than twice the adjusted total annual median cost ($1,283) of care (i.e., outpatient, specialty care, primary care, pharmacy and mental healthcare costs) than those with a low score ($609).[56] Treatment with effective pharmacotherapy can improve the QOL and functioning of these patients.[55]

Evaluation of Therapeutic Outcomes

During the acute phase of therapy, patients should be seen weekly for a month and then every other week. During months 3 to 6 of therapy, the patient can be seen monthly, and in months 6 to 12, visits can be extended to every 2 months. On each visit the patient should be asked about previously identified target symptoms of PTSD as well as other symptoms including insomnia, suicidal ideation, anger outbursts, irritability, psychosis, ongoing trauma, and disability. A remission in patients with PTSD is defined as a 70% or greater reduction in symptoms. Patients who have a 50% response or greater reduction in symptoms are considered to have an adequate response, while those with a 25% to 50% reduction in symptoms are considered partial responders.[29] Before deciding that a patient is not responsive to pharmacotherapy, the clinician should ensure that the medication trial has been adequate in both dose and duration.

Many patients with PTSD are sensitive to the adverse effects of drugs.[29] They should be monitored carefully for adverse reactions that can delay the escalation of drug dosages or cause the patient distress. Routine assessment of the metabolic profile is necessary if an atypical antipsychotic is used concurrently.[29] When pharmacotherapy is discontinued, patients should be seen more frequently and monitored carefully for signs of relapse or withdrawal.

TREATMENT

Obsessive-Compulsive Disorder

DESIRED OUTCOMES

Major goals of therapy for OCD include reduction in the frequency and severity of obsessive thoughts and time spent performing compulsive acts. Treatment for OCD generally does not completely

eliminate obsessions or compulsions, but patients can feel remarkably improved with partial resolution of symptoms. Optimal treatment increases psychosocial and occupational functioning and improves overall QOL. Efforts should be made to minimize adverse drug events and prevent drug interactions.

GENERAL APPROACH TO TREATMENT

It is important at the outset of therapy to identify and document the specific target symptoms for pharmacotherapy. Rating scales can be used to measure symptom severity at baseline and during treatment to ascertain the degree of improvement. The Yale-Brown Obsessive-Compulsive Scale (YBOCS) is the most widely used clinician-administered scale. A QOL scale can assist the clinician in identifying other areas to target for treatment (e.g., depression and reduced physical well-being).[57]

The Food and Drug Administration (FDA) has approved five antidepressants for the management of OCD: clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline. CBT and SSRIs are considered effective first-line treatment modalities.[58] Initial therapy may include CBT alone, SSRI monotherapy, or the combination of CBT and an SSRI, and is based on clinical judgment of symptom severity and patient preferences.[58] CBT alone can be used in cooperative patients who do not desire drug therapy, or those with mild anxiety or depressive symptoms. Patients unable to participate in CBT or with a prior history of medication therapy response should be treated with SSRI monotherapy. Combined CBT and SSRIs is recommended in patients with failure on an SSRI alone or in those with severe OCD. If a combination of CBT and an SSRI is unsuccessful, another SSRI should be tried before augmentation therapy. If there is no response or partial response to combined CBT and three adequate antidepressant trials (one of which is clomipramine), augmentation with another drug and more intensive CBT can be tried.[58] Augmentation with antipsychotics has proven efficacious in patients with partial response.[19–21,58]

CLINICAL CONTROVERSY

Patients with OCD who fail to respond to an initial trial of an SSRI are often switched to another SSRI. It is known that these patients are less likely to respond to venlafaxine.[58] There is a lack of data to predict the chance of response when switching to other medications such as mirtazapine or another SSRI.

Table 80–2 is a summary of key points from the treatment guidelines for OCD. Although some OCD symptoms can improve over the first few weeks of therapy, an adequate trial of any medication is considered to be 8 to 12 weeks at maximum tolerated dosage.

NONPHARMACOLOGIC TREATMENTS

A number of nonpharmacologic treatments are effective for OCD. CBT with behavioral techniques (e.g., exposure and response prevention [ERP], psychodynamic psychotherapy, and psychoanalysis) are the most common initial nonpharmacologic treatments of choice. Initially, 13-20 sessions are recommended. Clinicians can use motivational interviewing techniques to assist patients with treatment acceptance.[58]

Other options are transcranial magnetic stimulation (TMS), deep brain stimulation (DBS), and ablative neurosurgery. DBS is FDA-approved as a humanitarian device for severe, treatment-resistant OCD.[59] TMS and DBS should not be used alone as first-line treatments but may be added to CBT or used in refractory patients. Surgery should be reserved for rare cases.[58] Effects of ERP have been reported to last up to two years.[60]

TABLE 80-2 Summary of Key Points in Treatment Guidelines for OCD

Recommendation	Level of Evidence	Comments
First-line treatments		
CBT alone	I	13–20 sessions
SSRI alone	I	8–12 wk, at least 4–6 wk at maximum tolerated dose
CBT + SSRI	I	13–20 CBT sessions and 8–12 wk SSRI with 4–6 wk at maximum tolerated dose. If monotherapy with CBT or SSRI alone does not provide adequate response, combination therapy with CBT + SSRI should be tried before augmentation with another pharmacological agent
Second-line treatments		
Switch to another SSRI or clomipramine	I	
Augmentation with antipsychotic	II	
Third-line treatments		
Switch to another antipsychotic augmenting agent	II	
Augmentation of SSRI with clomipramine	III	
Maintenance and discontinuation phase		
After 1–2 years, gradual taper over several months	I	
Periodic CBT booster sessions for 3–6 months	II	

Levels of evidence:
[I] Recommended with substantial clinical confidence.
[II] Recommended with moderate clinical confidence.
[III] May be recommended on the basis of individual circumstances.
Data from American Psychiatric Association.[58]

PHARMACOLOGIC THERAPY

Practice Guidelines for the treatment of patients with OCD were published by the American Psychiatric Association.[58]

6 SSRIs are considered to be the drugs of choice for OCD.[58] While not FDA approved, escitalopram has also shown efficacy in reduction of OCD symptoms.[61] Clomipramine, a TCA with strong 5-HT reuptake inhibition, is also FDA approved for the treatment of OCD. Clomipramine has an active metabolite, desmethylclomipramine, which inhibits norepinephrine reuptake.[62] Meta-analytic findings of greater efficacy of clomipramine than SSRIs are not consistent with comparative trial data.[58]

Alternative Drug Treatments

Recent studies have examined the use of ondansetron, dextroamphetamine, caffeine, and D-cycloserine as possible augmentation agents in refractory OCD patients with mixed results. A study of ondansetron found 9 of 14 patients with OCD responded to ondansetron augmentation therapy.[63] In a study of caffeine and dextroamphetamine augmentation, YBOCS score decreases ranged

from 20% to 80% in the dextroamphetamine group and 27% to 89% in the caffeine group.[64] The number of exposure sessions necessary in patients treated with D-cycloserine was reduced compared with placebo initially.[65] These alternative treatments are reserved for refractory patients.[58]

Special Populations

Children and Adolescents OCD affecting children and adolescents is prevalent. There are symptom and treatment similarities and differences between OCD developing earlier in life and that which develops later. Younger patients exhibit poorer insight regarding obsessions, have more obsessions involving fear of harm and separation, and possess more rituals involving family members.[66] CBT provided in the group setting has been shown to be effective and is an alternative to individual CBT or medication treatment.[67] CBT weekly or daily and including family members has also been effective.[68] CBT and SSRI treatment are considered first-line for pediatric patients.[69]

Clomipramine, fluvoxamine, sertraline, paroxetine and fluoxetine are approved by the FDA for treatment of OCD in children and adolescents.[58] Childhood and adult OCD appear to respond similarly to drug therapy. SSRIs are effective and well tolerated in the treatment of OCD and are generally considered first-line agents.[58] Treatment with an SSRI produces a favorable response in 75% of children and adolescents with OCD. A combination of SSRI and CBT is preferred in most cases.[70] In children, the most commonly described side effects of SSRI therapy include nausea, headache, tremor, gastrointestinal complaints, drowsiness, akathisia, insomnia, disinhibition, and agitation.[70] The starting dose of clomimpramine in children is 25 mg daily in divided doses. The dose can be increased over the first 2 weeks up to 3 mg/kg or 100 mg, whichever is smaller. Over the next several weeks, the dose can be increased up to 3 mg/kg with a maximum of 200 mg daily.[62]

Hepatic and Renal Disease Clomipramine, fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram are extensively metabolized in the liver, and patients with significant liver disease should be prescribed these drugs cautiously and in lower doses than those used in healthy subjects. The pharmacokinetics of sertraline are not altered in patients with significant renal dysfunction, and dosage adjustment is not necessary in these patients.[36] Increased plasma concentrations of paroxetine occur in subjects with renal impairment.[35] The initial dose of paroxetine should be reduced in patients with severe renal impairment, and upward titration should occur more slowly.[35] No dosage adjustment is necessary for patients with renal impairment receiving clomipramine.[62]

Elderly Little information is available on treating OCD in the elderly. Case reports and anecdotal information suggest that the anti-obsessional drugs are likely to be equally effective in the elderly and in younger adults.[71] Selection of medication for an elderly person with OCD, however, should be based on history of response and adverse side-effect profile. Treatment should be initiated with low doses in elderly patients, and doses should be increased slowly, with vigilance for emergence of side effects.[58] Because of clomipramine's sedative and anticholinergic side effects, it is not usually chosen as first-line therapy for elderly OCD patients.[58] The safety of fluvoxamine has not been adequately studied in the elderly and patients with cardiovascular disease. Dosage should be reduced and titrated slowly during initiation of fluvoxamine therapy in elderly patients.

Sertraline plasma clearance in elderly patients was approximately 40% lower than in a group of younger individuals. Clearance of desmethylsertraline was also decreased in elderly men but not in elderly women.[36] In a multiple-dose study in the elderly, the minimal concentrations of paroxetine were 70% to 80% greater than in nonelderly subjects. The manufacturer recommends that the initial dose be reduced in the elderly (10 mg/day), and total daily doses should not exceed 40 mg.[35] The use of SSRIs in elderly patients is discussed in Chapter 77.

Pregnancy Risk-benefit analysis should be made by practitioners when deciding to use pharmacotherapy options during pregnancy.[58] The use of SSRIs in pregnancy and lactation is discussed in the chapter on depression (Chapter 77).

Antidepressant Therapy

Serotonergic Antidepressants The only potent 5-HT reuptake inhibitors consistently demonstrating efficacy in controlled trials are the TCA clomipramine and the SSRIs fluoxetine, fluvoxamine, paroxetine, and sertraline. Forty percent to 60% of patients with OCD respond to a serotonergic antidepressant. Improvement in symptoms is incomplete, and ranges from 20% to 40%. Most patients continue to have symptoms that limit their functioning.[27] Ten to 12 weeks constitute an adequate treatment period.[27]

Current evidence indicates that 5-HT is important for the anti-obsessional effects of medication. SSRIs and clomipramine inhibit 5-HT reuptake into the presynaptic neuron. Inhibiting reuptake of 5-HT makes more 5-HT available to postsynaptic receptors and reduces formation of the 5-HT metabolite 5-hydroxyindoleacetic acid. Although other antidepressants, such as imipramine and amitriptyline, inhibit 5-HT reuptake, they are less potent and selective than SSRIs. Prolonged exposure to increased amounts of 5-HT after chronic antidepressant treatment (2–3 weeks) leads to altered responsiveness of postsynaptic 5-HT receptors or presynaptic autoregulatory receptors that govern 5-HT release in specific brain regions. An improvement in obsessional symptoms may correlate with plasma concentrations of clomipramine but not desmethylclomipramine, the metabolite of clomipramine with less selectivity for 5-HT reuptake inhibition.

Most experts agree that SSRIs are better tolerated than clomipramine. SSRIs are less likely to cause cardiovascular, sedative, anticholinergic, and weight-gain side effects. Clomipramine is less likely than SSRIs to cause insomnia, akathisia, nausea, and diarrhea. Antidepressant side effects can be more severe when larger doses are used and with faster dose escalation. Tolerance to antidepressant adverse effects often develops over 6 to 8 weeks of treatment, and tolerance is more likely to develop to nausea, diarrhea, sedation, diminished libido and/or orgasm, anxiety, restlessness, insomnia, and anticholinergic side effects than to akathisia.[71]

Pharmacokinetics Clomipramine is rapidly absorbed following oral administration. Maximum plasma concentrations occur within 3 to 8 hours. It is highly protein-bound (greater than 90%) in the blood and has a half-life of 15 hours.[71] The drug is metabolized to desmethylclomipramine, which is pharmacologically active. The pharmacokinetics of SSRIs are discussed in Chapter 77.

Efficacy SSRIs are effective in the treatment of OCD. Well-designed trials comparing these medications with placebo, head-to-head comparative trials, and meta-analyses have established that fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, and escitalopram are equally effective and that clomipramine may be somewhat more effective.[15,61]

Other Antidepressants Venlafaxine, which acts as a serotonin and norepinephrine reuptake inhibitor, may be effective for OCD.[71]

Augmentation with Antipsychotics Augmentation of SSRI treatment with low doses of risperidone, quetiapine, or olanzapine may be helpful. Typical antipsychotics are generally not recommended because of an increased likelihood of extrapyramidal symptoms.[71,72] Risperidone, quetiapine, and olanzapine augmentation has the most evidence with response rates in the range of 40% to 50%.[19–21,58]

TABLE 80-3 Dosing of Serotonin Reuptake Inhibitors in the Treatment of Obsessive-compulsive Disorder

Generic Name	Usual Initial Daily Dose (mg)	Usual Target Daily Dose (mg)	Usual Maximum Daily Dose (mg)
Citalopram[a,b]	20	40–60	80
Clomipramine[a]	25	100–250	250
Escitalopram[b]	10	20	40
Fluoxetine[a]	20	40–60	80
Fluvoxamine[a]	50	200	300
Paroxetine[a]	20	40–60	60
Sertraline[a]	50	200	200

[a]Available generically.
[b]Not FDA approved for treatment of obsessive-compulsive disorder. Optimal dosing guidelines are not well established.
Data from American Psychiatric Association Practice Guideline,[58] Paxil package insert,[35] Zoloft package insert,[36] and Anafranil package insert.[62]

Dosage and Administration Table 80–3 summarizes dosing guidelines for SSRIs and clomipramine. If there is inadequate response to an average dose, then it should be incrementally increased to the maximum dose within 5 to 9 weeks from the start of treatment. 7 If there is an inadequate response after 4 to 6 weeks at the maximum dose, then another SSRI should be tried.[58] Eight to 12 weeks is considered an adequate trial before changing to another drug or augmenting with another agent.

Although the appropriate maintenance dose of antidepressants is unknown, it is notable that one investigator was successful in reducing the dose of clomipramine from a mean of 270 mg/day to 165 mg/day in the maintenance phase.[73]

PHARMACOECONOMIC CONSIDERATIONS

The annual outpatient direct cost for treatment of OCD in the United States in 1995 was $5.1 billion. In 1990, the total cost to the economy was $8 billion, which included expenditures for direct ($2.1 billion) and indirect costs. Direct costs included costs of hospitalization, outpatient professional services, and drugs. Indirect costs were costs associated with lost productivity, work loss, early retirement, and absenteeism. As OCD frequently has its onset in childhood or adolescence, loss of income over a lifetime is substantial.[74]

Another pharmacoeconomic consideration that impacts the provision of optimal treatment for patients with OCD relates to inability to pay for nonpharmacologic therapy. Although CBT has been shown to be a very effective modality, very often the patient cannot afford this therapy or does not have medical insurance that helps pay the associated costs.

EVALUATION OF THERAPEUTIC OUTCOMES

Target symptoms of OCD should be monitored closely. The degree of response can indicate a need to modify dosage, change drug, or augment therapy. Rating scales can be used to monitor symptom response to therapy for OCD (e.g., YBOCS) and changes in QOL. The clinician should inquire about and address problematic adverse effects (including the emergence of suicidal ideation) reported by the patient. Changes in social and occupational functioning should be assessed.

Patients older than 40 years of age should receive a pretreatment electrocardiogram before starting clomipramine. In patients with liver disease, baseline and periodic liver function tests are recommended when clomipramine is used. Patients receiving clomipramine who develop fever and sore throat should have leukocyte and differential white blood cell counts assessed to evaluate for agranulocytosis.

After patients have responded to the acute phase of treatment, treatment gains are maintained with maintenance-phase strategies.

8 Monthly follow-up visits are recommended for at least 3 to 6 months, and a medication taper can be considered after 1 to 2 years of treatment. Medication should not be rapidly discontinued, and booster CBT sessions can reduce the risk of relapse when medication is withdrawn. The drug dosage can be decreased by 10% to 25% every 1 to 2 months with careful observation for symptom relapse.[58] Some patients require lifelong medication therapy.

CONCLUSIONS

The past decade has brought a renewed interest in the recognition and management of PTSD. Healthcare workers are sensitized to the devastating effects that PTSD can have on patient functioning and QOL. Adequately detecting and appropriately managing PTSD is important to improving the lives of patients who suffer from this illness. Data on the efficacy of SSRIs, SNRIs, and various augmenting agents support their use in achieving treatment remission. SSRIs are the first-line pharmacotherapy of PTSD and OCD. Research in OCD has resulted in new pharmacologic treatment strategies, especially with augmentation therapies.

ABBREVIATIONS

ASD: acute stress disorder
CBT: cognitive behavioral therapy
CRF: corticotrophin-releasing factor
DA: dopamine
DBS: deep brain stimulation
EMDR: eye movement desensitization and reprocessing
ERP: exposure and response prevention
FDA: U.S. Food and Drug Administration
5-HT: serotonin
GABA: γ-aminobutyric acid
HPA: hypothalamic-pituitary-adrenal
MAOI: monoamine oxidase inhibitor
NE: norepinephrine
NPY: neuropeptide Y
OCD: obsessive-compulsive disorder
PANDAS: pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection
PTSD: posttraumatic stress disorder
QOL: quality of life
SNRI: serotonin-norepinephrine reuptake inhibitor
SSRI: selective serotonin reuptake inhibitor
TCA: tricyclic antidepressant
TFCBT: trauma-focused cognitive behavioral therapy
TMS: transcranial magnetic stimulation
vmPFC: ventromedial prefrontal cortex
YBOCS: Yale-Brown Obsessive Compulsive Scale

CHAPTER 81

Sleep Disorders

JOHN M. DOPP AND BRADLEY G. PHILLIPS

KEY CONCEPTS

1. Common causes of insomnia include concomitant psychiatric disorders, significant psychosocial stressors, excessive alcohol use, caffeine intake, and nicotine use.
2. Good sleep hygiene, including relaxing before bedtime, exercising regularly, establishing a regular bedtime and wake-up time, and discontinuing alcohol, caffeine, and nicotine, alone and in combination with drug therapy, should be part of patient education and treatments for insomnia.
3. Long-acting benzodiazepines should be avoided in the elderly.
4. Benzodiazepine tolerance and dependence are avoided by using low-dose therapy for the shortest possible duration.
5. Obstructive sleep apnea may be an independent risk factor for the development of hypertension. When hypertension is present, it is often refractory to drug therapy until sleep-disordered breathing is alleviated.
6. Nasal continuous positive airway pressure is the first-line therapy for obstructive sleep apnea, and weight loss should be encouraged in all obese patients.
7. Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness and cataplexy.
8. Short-acting benzodiazepine receptor agonists or melatonin taken at appropriate target bedtimes for east or west travel reduce jet lag and shorten sleep latency.
9. Dopamine agonists are effective for restless legs syndrome and have replaced levodopa as first-line therapy.

Approximately 70 million Americans suffer with a sleep-related problem, and as many as 60% of those experience a chronic disorder.[1] In a study by the National Institute of Aging, of 9,000 patients age 65 years and older, more than 80% report a sleep-related disturbance.[1]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

INTRODUCTION TO SLEEP

SLEEP CYCLES

Sleep is divided into two phases: nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Humans typically experience four to six cycles of NREM and REM sleep, with each cycle lasting between 70 and 120 minutes.[2] There are four stages of NREM sleep. Healthy sleep will typically progress through the four stages of NREM sleep prior to the first REM period. From wakefulness, sleep typically progresses quickly through stages 1 and 2. Stage 1 of NREM sleep is the stage between wakefulness and sleep, and individuals describe this experience as being awake, being drowsy, or being asleep. During stages 3 and 4 NREM, both metabolic activity and brain waves slow. This slow-wave sleep occurs most frequently early in the sleep period. Stage 3 and stage 4 sleep are called *delta sleep,* as the sleep is characterized by high-amplitude slow activity known as delta waves (0.5–3 Hz). In this stage eye movements are absent, and muscle tone is atonic.[3]

REM sleep involves a dramatic physiologic change from NREM sleep, to a state in which the brain becomes electrically and metabolically activated.[2] REM occurs in bursts and is accompanied by a 62% to 173% increase in cerebral blood flow, generalized muscle atonia, bursts of bilateral rapid eye movements, poikilothermia, dreaming, and fluctuations in respiratory and cardiac rate.[2] REM cycles tend to lengthen in the later stages of the sleep cycle.[2]

CIRCADIAN RHYTHM

At birth human infants spend up to 20 hours a day sleeping. At 3 to 6 months of age there is a differentiation between REM and NREM sleep. By age 3 the ultradian sleep–wake rhythm changes to a circadian pattern. The suprachiasmatic nucleus of the brain serves as the biologic clock and paces the circadian rhythm. Although the length of a day is 24 hours, in environments devoid of light cues, the sleep–wake cycle lasts 24.2 hours.[3] In midlife, there is a gradual decline in sleep efficiency and sleep time.[2] The elderly have lighter and more fragmented sleep, with intermittent arousals, shifts in the sleep stages, and a gradual reduction of slow wave sleep.

NEUROCHEMISTRY

The neurochemistry of sleep is complex as sleep cannot be localized to either a specific area of the brain or a neurotransmitter. NREM sleep appears to be controlled by the basal forebrain, the area surrounding the solitary tract in the medulla and the dorsal raphe nucleus, which is primarily serotonergic.[3] Sleep is reduced when there are decreases in serotonin or destruction of the dorsal raphe nucleus in the brainstem, which contains most of the

brain's serotonergic bodies. REM sleep appears to be turned on by cholinergic cells in the mesencephalic, medullary, and pontine gigantocellular regions. REM sleep appears to be turned off by the dorsal raphe nucleus, the locus coeruleus, and the nucleus parabrachialis lateralis, the latter two of which are primarily noradrenergic. The ascending reticular activating system and the posterior hypothalamus facilitate arousal and wakefulness.[4] Dopamine has an alerting effect; decreases in dopamine promote sleepiness.[5] Neurochemicals involved in wakefulness include norepinephrine and acetylcholine in the cortex and histamine and neuropeptides such as substance P and corticotropin-releasing factor in the hypothalamus.[5,6]

POLYSOMNOGRAPHY

Sleep is typically measured and observed in sleep laboratories using an electroencephalogram (EEG), electro-oculograms of each eye, electrocardiogram, electromyogram, air thermistors, abdominal and thoracic strain belts, and oxygen saturation monitor. This study is named polysomnography (PSG) and is used to assess and record variables that characterize sleep and aid in diagnosis of sleep disorders. Variables obtained during PSG include sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, arrhythmias, airflow during sleep, respiratory effort, and oxygen desaturations.

CLASSIFICATION OF SLEEP DISORDERS

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* classifies sleep disorders into four categories based on etiology and requires a minimum of 1 month before a sleep disorder can be diagnosed.[7,8] Primary sleep disorders are those disorders in which there is no other etiology (mental disorder, substance-related disorder, or medical condition) responsible for the disorder. Primary sleep disorders appear to be based on an endogenous abnormality of the sleep–wake cycle, or circadian rhythm, and they are divided into dyssomnias (abnormality in the amount, quality, or timing of sleep) or parasomnias (abnormal behavioral or physiologic events associated with sleep, e.g., sleepwalking and REM behavior disorder). Dyssomnias include sleep disorders such as insomnia, narcolepsy, obstructive sleep apnea, and circadian rhythm disorders.

INSOMNIA

Insomnia is the most common complaint in general medical practice.[9] It causes distress, frequently because of a fear or a feeling of not being able to fall asleep at bedtime, and can impair work-related productivity because of daytime fatigue or drowsiness. Insomnia is subjectively characterized as a complaint of difficulty falling asleep, difficulty maintaining sleep, or experiencing nonrestorative sleep.[8] Insomnia lasting two or three nights because of jet lag, for example, is considered to be transient insomnia, whereas short-term insomnia usually resolves in less than 3 weeks. Insomnia, according to the *DSM-IV-TR*, is considered to be chronic when it lasts longer than 1 month.[8]

Epidemiology

Primary insomnia usually begins in early or middle adulthood and is rare in childhood or adolescence. More than 50% of the population complains of insomnia in their lifetime.[1] A 1-year prevalence study of insomnia in the United States reports that one third of the individuals surveyed complained of insomnia, and 17% reported that the symptoms were serious.[1] Conservative estimates of chronic insomnia range from 9% to 12% in adulthood and up to 20% in the elderly.[1,10] Although young adults are more likely to complain that they have difficulty falling asleep, middle-aged and elderly adults are more likely to complain that they have middle-of-the-night awakening or early morning awakening. Women complain of insomnia twice as frequently as men. Individuals who are elderly, unemployed, separated, or widowed, and those with a lower socioeconomic status reported a significantly higher incidence of insomnia than the general population. Forty percent of individuals with insomnia also had a concurrent psychiatric disorder (anxiety, depression, or substance abuse).[9]

Despite the prevalence of insomnia, only 5% of individuals seek medical attention for management of their insomnia. Approximately 10% to 20% of those with insomnia use nonprescription drugs or alcohol to self-treat. Of the 3% of the population who are prescribed sedative–hypnotics for insomnia, 11% report use exceeding 1 year.[11]

Differential Diagnosis

Primary insomnia is considered to be an endogenous disorder caused by either a neurochemical or a structural disorder affecting the sleep–wake cycle. Individuals with primary insomnia can be light sleepers who are easily aroused by noise, temperature, or anxiety. Some studies suggest that primary insomnia is a "hyperarousal state," in that insomnia patients have increased metabolic rates compared with controls and thus take longer to fall asleep.[2] Comorbid insomnia is frequently a symptom or manifestation of another medical disorder. Evaluation of patients with a complaint of transient or short-term insomnia should focus on recent stressors, such as a separation, a death in the family, a job change, or college exams.

1 Chronic insomnia is frequently comorbid with psychiatric or medical conditions. A complete diagnostic examination should be completed in these individuals and should include routine laboratory tests, physical and mental status examinations, as well as ruling out any medication- or substance-related causes.[12] Special consideration should also be given to other sleep disorders that can have a similar presentation, including restless legs syndrome, periodic limb movements of sleep, and sleep apnea. Common causes of insomnia are listed in Table 81–1.

TABLE 81-1 Common Etiologies of Insomnia

Situational
Work or financial stress, major life events, interpersonal conflicts
Jet lag or shift work
Medical
Cardiovascular (angina, arrhythmias, heart failure)
Respiratory (asthma, sleep apnea)
Chronic pain
Endocrine disorders (diabetes, hyperthyroidism)
Gastrointestinal (gastroesophageal reflux disease, ulcers)
Neurologic (delirium, epilepsy, Parkinson disease)
Pregnancy
Psychiatric
Mood disorders (depression, mania)
Anxiety disorders (e.g., generalized anxiety disorder, obsessive-compulsive disorder)
Substance abuse (alcohol or sedative-hypnotic withdrawal)
Pharmacologically induced
Anticonvulsants
Central adrenergic blockers
Diuretics
Selective serotonin reuptake inhibitors
Steroids
Stimulants

TREATMENT

Insomnia

Therapeutic management of insomnia is initially based on whether the individual has experienced a transient, short-term, or chronic sleep disturbance. Clinical history should assess the onset, duration, and frequency of the symptoms; effect on daytime functioning; sleep hygiene habits; and history of previous symptoms or treatment.[13] Management of all patients with insomnia should include identifying the cause of the insomnia, patient education on sleep hygiene, and stress management. Any unnecessary pharmacotherapy should be eliminated.[10] Transient insomnia, which occurs as a result of an acute stressor, is expected to resolve quickly and should be treated with good sleep hygiene and careful use of sedative-hypnotics.[14] Short-term insomnia, associated with situational, personal, or medical stress can be treated similarly.[13] Chronic insomnia requires careful assessment for possible underlying medical causes, nonpharmacologic techniques, and careful use of sedative-hypnotics.[12]

NONPHARMACOLOGIC THERAPY

2 In many cases insomnia can be treated without sedative-hypnotics. Education about normal sleep and habits for good sleep hygiene are often sufficient interventions.[2] Nonpharmacologic interventions for insomnia frequently consist of short-term cognitive behavioral therapies, most commonly stimulus control therapy, sleep restriction, relaxation therapy, cognitive therapy, paradoxical intention, and education on good sleep hygiene (Table 81–2).[10,15,16] In patients age 55 and older, research indicates that cognitive behavioral therapy may be more effective than pharmacologic therapy at improving certain measures of insomnia.[17]

TABLE 81-2 Nonpharmacologic Recommendations for Insomnia

Stimulus control procedures

1. Establish regular times to wake up and go to sleep (including weekends).
2. Sleep only as much as necessary to feel rested.
3. Go to bed only when sleepy. Avoid long periods of wakefulness in bed. Use the bed only for sleep or intimacy; do not read or watch television in bed.
4. Avoid trying to force sleep; if you do not fall asleep within 20–30 minutes, leave the bed and perform a relaxing activity (e.g., read, listen to music, or watch television) until drowsy. Repeat this as often as necessary.
5. Avoid daytime naps.
6. Schedule worry time during the day. Do not take your troubles to bed.

Sleep hygiene recommendations

1. Exercise routinely (three to four times weekly) but not close to bedtime because this can increase wakefulness.
2. Create a comfortable sleep environment by avoiding temperature extremes, loud noises, and illuminated clocks in the bedroom.
3. Discontinue or reduce the use of alcohol, caffeine, and nicotine.
4. Avoid drinking large quantities of liquids in the evening to prevent nighttime trips to the restroom.
5. Do something relaxing and enjoyable before bedtime.

CLINICAL CONTROVERSY

Pharmacologic treatment is indicated for transient and short-term insomnia. Historically, the use of sedative hypnotic agents for greater than 1 month was frowned on and discouraged in fear of fostering drug dependence. Experts now agree that clinicians should encourage hypnotic therapy using the lowest effective dose for the shortest duration possible. However, long-term use of hypnotics is not contraindicated unless the patient has another contraindication (e.g., history of substance abuse, pregnancy, etc.).

PHARMACOLOGIC THERAPY

Miscellaneous Agents

Antihistamines exhibit sedating properties and are included in many over-the-counter sleep agents. They are effective in the treatment of mild insomnia and are generally safe.[13] Diphenhydramine and doxylamine are more sedating than pyrilamine. Increasing the dose of antihistamines will not produce a linear increase in response. The safety and efficacy of antihistamines over placebo have been documented in several studies. Antihistamines are considered to be less effective than benzodiazepines, and they have the disadvantages of anticholinergic side effects, which are especially troublesome in the elderly.[13,18]

Antidepressants are alternatives for patients with nonrestorative sleep who should not receive benzodiazepines, especially those who have depression, pain, or a risk of substance abuse. Using antidepressants for insomnia without depression is common but not well studied, and the doses used for treating insomnia are not effective antidepressant doses.[18] Sedating antidepressants such as amitriptyline, doxepin, and nortriptyline are effective for inducing sleep continuity, although daytime sedation and side effects can be significant.[18] Anticholinergic activity, adrenergic blockage, and cardiac conduction prolongation can be problematic, especially in the elderly and in overdose situations.[18] Mirtazapine is a sedating antidepressant that may help patients sleep, but it may also cause daytime sedation and weight gain.

Trazodone in doses of 25 to 100 mg at bedtime is sedating and can improve sleep continuity.[11] Trazodone is popular for the treatment of insomnia in patients prone to substance abuse, as dependence is not a problem. Trazodone is frequently used in patients with selective serotonin reuptake inhibitor (SSRI) and bupropion-induced insomnia.[11] Caution should be used to avoid serotonin syndrome when used in these combinations. Other side effects include carryover sedation and α-adrenergic blockade. Orthostasis can occur at any age, but it is more dangerous in the elderly. Priapism is a rare but serious side effect.[19]

Ramelteon is a melatonin receptor agonist approved for the treatment of sleep onset insomnia. Ramelteon is selective for the MT1 and MT2 melatonin receptors that are thought to regulate the circadian rhythm and sleep onset. The recommended dose is 8 mg taken at bedtime to induce sleep. Although generally well tolerated, the most common adverse events reported are headache, dizziness, and somnolence. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse.

Valerian is an herbal sleep remedy that has been studied for its sedative-hypnotic properties in patients with insomnia. The mechanism of action is not fully understood but may involve increasing concentrations of γ-aminobutyric acid (GABA). The recommended dose for insomnia ranges from 300 to 600 mg. An equivalent dose of dried herbal valerian root is 2 to 3 g soaked in 1 cup of hot water for 20 to 25 minutes.[20]

CLINICAL CONTROVERSY

The over-the-counter supplement melatonin is a popular treatment for insomnia. Although melatonin has demonstrated efficacy for inducing sleep, its use for the treatment of insomnia is not well supported by clinical studies. Further research is needed before melatonin can be recommended for the treatment of insomnia.

TABLE 81-3 Pharmacokinetics of Benzodiazepine Receptor Agonists

Generic Name (Brand Name)	t_{max} (Hours)[a]	Half-Life[b] (Hours)	Daily Dose Range (mg)	Metabolic Pathway	Clinically Significant Metabolites
Estazolam (ProSom)	2	12–15	1–2	Oxidation	–
Eszopiclone (Lunesta)	1–1.5	6	2–3	Oxidation Demethylation	–
Flurazepam (Dalmane)	1	8	15–30	Oxidation *N*-dealkylation	Hydroxyethylflurazepam, flurazepam aldehyde N-desalkylflurazepam[c]
Quazepam (Doral)	2	39	7.5–15	Oxidation, *N*-dealkylation	2-Oxo-quazepam, N-desalkylflurazepam[c]
Temazepam (Restoril)	1.5	10–15	15–30	Conjugation	–
Triazolam (Halcion)	1	2	0.125–0.25	Oxidation	–
Zaleplon (Sonata)	1	1	5–10	Oxidation	–
Zolpidem (Ambien)	1.6	2–2.6	5–10	Oxidation	–

[a]Time to peak plasma concentration.
[b]Half-life of parent drug.
[c]*N*-desalkylflurazepam, mean half-life 47 to 100 hours.

Benzodiazepine Receptor Agonists

The most commonly used treatments for insomnia have been the benzodiazepine receptor agonists. All benzodiazepine receptor agonists are effective as sedative-hypnotics and are FDA labeled for the treatment of insomnia (Table 81–3). The FDA recently required benzodiazepine receptor agonist labeling to include a caution regarding anaphylaxis, facial angioedema, and complex sleep behaviors (e.g., sleep driving, phone calls, sleep eating, etc.). The benzodiazepine receptor agonists consist of the newer nonbenzodiazepine $GABA_A$ agonists and the traditional benzodiazepines. All benzodiazepine receptor agonists bind to $GABA_A$ receptors in the brain, resulting in stimulatory effects on GABAergic transmission and hyperpolarization of neuronal membranes. Traditional benzodiazepines have sedative, anxiolytic, muscle relaxant, and anticonvulsant properties; newer nonbenzodiazepine GABA agonists possess only sedative properties.

Benzodiazepine Hypnotics

Benzodiazepines relieve insomnia by reducing sleep latency and increasing total sleep time. Benzodiazepines increase stage 2 sleep while decreasing REM, stage 3, and stage 4 sleep.[11] Benzodiazepine hypnotics should not be prescribed for individuals who are pregnant or who have untreated sleep apnea or a history of substance abuse. Patients should be instructed to avoid alcohol and other CNS depressants.

Pharmacokinetics The choice of a particular benzodiazepine can be based on its pharmacokinetic profile. When used as a single dose, extent of distribution and elimination half-life are important in predicting the duration of action. However, after multiple doses, the elimination half-life and formation of active metabolites determine the extent of drug accumulation and resultant clinical effects.[11] Advanced age, liver dysfunction, and drug interactions can prolong drug effects. The pharmacokinetic profiles of benzodiazepine receptor agonists are summarized in Table 81–3.

Adverse Effects Side effects are dose dependent and vary according to the pharmacokinetics of the individual benzodiazepine. High doses with long or intermediate elimination half-lives have a greater potential for producing daytime sedation, psychomotor incoordination, decreased concentration, and cognitive deficits. Tolerance to benzodiazepine hypnotic effects develops sooner with triazolam (after 2 weeks of continuous use) than with other benzodiazepine hypnotics.[11] Most traditional benzodiazepines maintain hypnotic efficacy for 1 month. However, tolerance can develop with time. Rapidly eliminated benzodiazepines have less potential for daytime sedation.[11]

Anterograde amnesia, an impairment of memory and recall of events occurring after the dose is taken, has been reported with most benzodiazepine receptor agonists.[11] Rebound insomnia, characterized by increased wakefulness beyond baseline amounts that last for 1 to 2 nights after abrupt discontinuation, occurs with benzodiazepine receptor agonists. Rebound insomnia occurs more frequently after high doses of triazolam, even when ingested intermittently.[11] The lowest effective dosage should be used to minimize rebound insomnia and avoid adverse effects on memory.

3 Benzodiazepine half-lives are prolonged in older patients, increasing the potential for drug accumulation and the incidence of CNS side effects, including prolonged sedation and cognitive and psychomotor impairment. Benzodiazepine receptor agonists with long elimination half-lives are generally not first-line agents in these patients. There is an association between falls and hip fractures and the use of benzodiazepines with long elimination half-lives; thus flurazepam and quazepam should be avoided in elderly patients.[21]

Nonbenzodiazepine $GABA_A$ Agonists

Zolpidem, zaleplon, and eszopiclone are nonbenzodiazepine hypnotics that selectively bind to $GABA_A$ receptors and effectively induce sleepiness. Zolpidem, an imidazopyridine chemically unrelated to benzodiazepines or barbiturates, has a duration of action of 6 to 8 hours.[22] It is comparable in efficacy to benzodiazepine hypnotics and is effective for reducing sleep latency and nocturnal awakenings and increasing total sleep time. It does not appear to have significant effects on next-day psychomotor performance. A sustained release formulation of zolpidem is now available that is effective at increasing total sleep time and reducing wakefulness after sleep onset without significant carryover sedation.

The safety and efficacy of zolpidem for insomnia is similar to that of the benzodiazepines. Zolpidem is less disruptive of sleep stages than benzodiazepines. Adverse effects are dose related and can include drowsiness, amnesia, dizziness, headache, and gastrointestinal complaints.[22] Several cases of brief psychotic reactions have been reported in women, and recent reports of sleep-eating during zolpidem therapy have caused significant weight gain.[22] The recommended daily dose of zolpidem is 10 mg or 5 mg in elderly patients and those with hepatic impairment. The dosage can be increased to 20 mg per night.[22] Because food decreases its absorption, zolpidem should be taken on an empty stomach.[23]

Zaleplon is a pyrazolopyrimidine and has a rapid onset of action and a half-life of 1 hour, and it is metabolized to inactive metabolites.[24] It is effective for decreasing time to sleep onset but not for reducing nighttime awakening or for increasing total sleep time.[25] Because of its short half-life, zaleplon has no effect on next-day

psychomotor performance and can be best used as a sleep aid for middle-of-the-night awakenings.[26] The recommended dose is 10 mg in adults and 5 mg in the elderly.[24] The most common adverse effects with zaleplon are dizziness, headache, and somnolence. There are two drug interactions of note: zaleplon plasma levels are increased when combined with cimetidine and decreased with rifampin.[22]

Eszopiclone is a pyrrolopyrazine hypnotic with a rapid onset of action and a half-life of 5 to 6 hours.[27] It is effective at reducing time to sleep onset, wake time after sleep onset, and number of awakenings, and increasing total sleep time and sleep quality. Eszopiclone's duration of action is up to 6 hours,[27] so it can be a better option for treatment of sleep maintenance insomnia or early morning awakenings than zaleplon. The most common adverse effects with eszopiclone are somnolence, unpleasant taste, headache, and dry mouth.[28] Eszopiclone is labeled for long-term use and may be taken nightly for up to 6 months.[28]

Other Considerations

In general, the nonbenzodiazepine hypnotics seem to be associated with less withdrawal, tolerance, and rebound insomnia than the benzodiazepine hypnotics. None of the nonbenzodiazepine $GABA_A$ agonists have significant active metabolites.

EVALUATION OF THERAPEUTIC OUTCOMES

An algorithm for the evaluation and treatment of sleep disorders is shown in Figure 81–1. Patients with short-term or chronic insomnia should be evaluated after 1 week of therapy to assess for drug efficacy, adverse effects, and adherence to nonpharmacologic recommendations.

Patients should be instructed to keep a sleep diary. The diary requires daily recording of bedtime, wake time, latency of sleep onset, number and duration of awakenings, medication ingestion, naps, and an index of sleep quality. For patients with chronic insomnia, possible medical, psychiatric, and pharmacologic causes should be identified and managed.[11] Patients with insomnia should receive education about possible medication side effects and their management. Prescriptions for benzodiazepine receptor agonists should be accompanied by printed information and verbal counseling on precautions.

4 Clinicians should educate patients about the concepts of tolerance, withdrawal, and rebound insomnia. Tolerance and dependence can be avoided by using hypnotics at the lowest possible dose, intermittently, and for the shortest duration possible. Patients should receive instruction on the initiation of therapy about frequency of drug use and the expected duration of therapy, to help prevent development of dependence. Withdrawal symptoms can be diminished by tapering the dosage gradually.

SLEEP APNEA

Approximately 15 million Americans have sleep-disordered breathing.[29] The prevalence of sleep apnea in the U.S. adult population is 4% in males and 2% in females.[30] It appears to be more common in African Americans and less common in Asian populations. Sleep apnea also occurs in children and adolescents. It is characterized by repetitive episodes of cessation of breathing during sleep followed by blood oxygen desaturation and brief arousal from sleep to restart breathing. As a result, individuals with sleep apnea experience fragmented sleep, poor sleep architecture, and periods of apnea

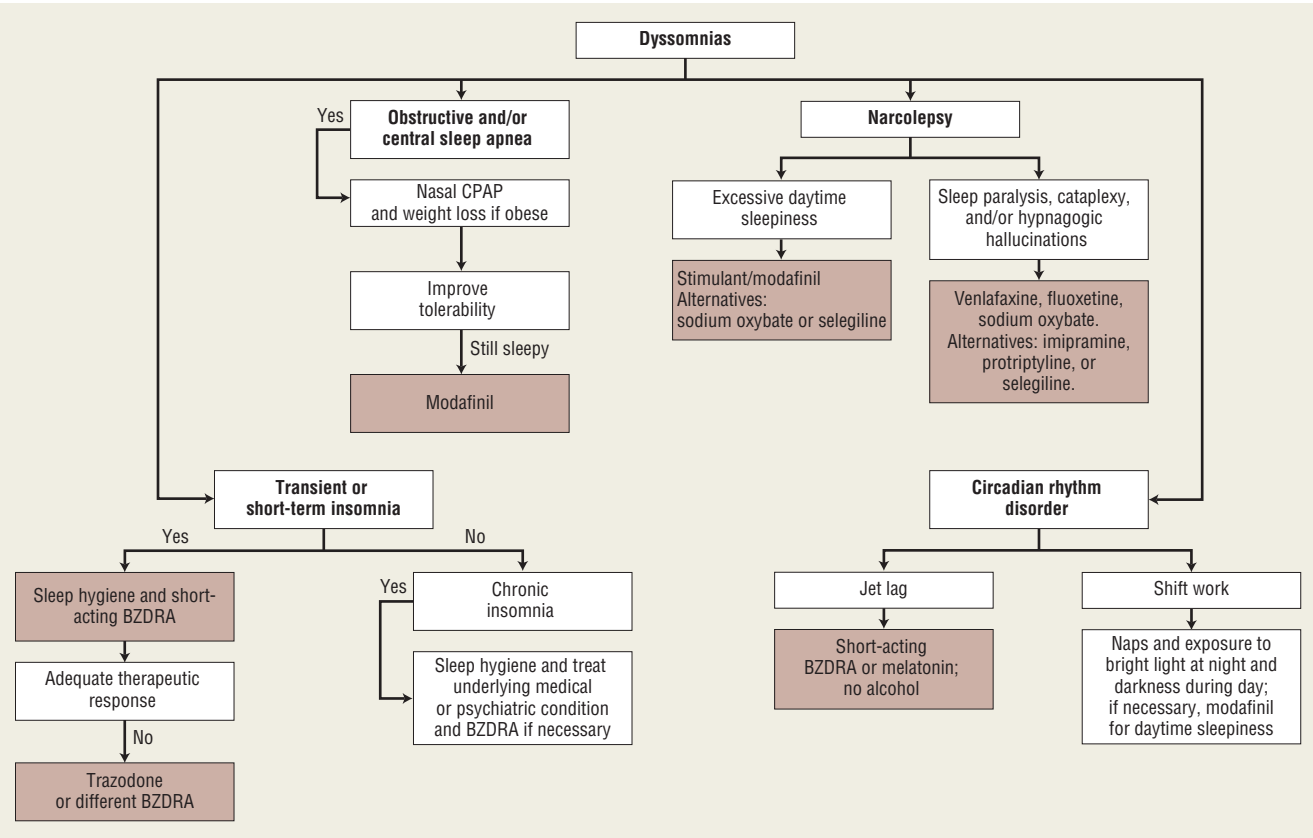

FIGURE 81-1. Algorithm for treatment of dyssomnias. (BZDRA, benzodiazepine receptor agonist; CPAP, continuous positive airway pressure.) *(Modified with permission from Jermaine DM. Sleep Disorders. In: Carter BL, Angaran DM, Lake KD, Raebel MA, eds. Pharmacotherapy Self-Assessment Program, 2nd ed. Neurology and Psychiatry. Kansas City: American College of Clinical Pharmacy, 1995;146–147.)*

and hypopnea. Polysomnography (PSG) is used to diagnose and quantify sleep apnea as central, obstructive, or mixed. Central sleep apnea (CSA) involves impairment of the respiratory drive, whereas obstructive sleep apnea (OSA) is caused by upper airway collapse and obstruction. Patients with mixed sleep apnea experience both central and obstructive sleep apnea. Severity of sleep apnea is determined by the number of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) episodes documented by PSG, and is expressed by calculating the respiratory disturbance index (RDI). Mild sleep apneics have an RDI of between 5 and 15 episodes per hour, moderate 15 to 30, whereas individuals with severe OSA can exhibit more than 30 episodes per hour.

Sleep apnea can affect behavior, cognitive abilities, and systemic disease.[31] Neurocognitive sequelae are important factors in motor vehicle accidents, loss of work-related productivity, and personality changes.[31,32] Alleviation of sleep disordered breathing can have a beneficial impact on both cardiovascular and neurobehavioral conditions.[33]

OBSTRUCTIVE SLEEP APNEA

OSA is characterized by partial or complete closure of the upper airway, posterior from the nasal septum to the epiglottis, during inspiration. The reason for the loss of upper airway patency is not fully understood and is likely caused by several competing factors. Anatomical factors including neck obesity, narrow airway, and fixed upper airway lesions (e.g., polyps, enlarged tonsils) can narrow the upper airway. Intraluminal negative pressure generated during each inspiration also promotes collapse of the upper airway that competes with dilating forces, primarily the pharyngeal dilator muscle. Acromegaly, amyloidosis, and hypothyroidism as well as neurologic conditions that impair upper airway muscle tone may cause OSA. The hallmarks of OSA are witnessed apneas, gasping, or both. Other recognized signs, symptoms, and considerations of sleep apnea include obesity, snoring, hypertension, daytime sleepiness, and family history.

5 OSA is increasingly linked to cardiovascular and cerebrovascular morbidity and mortality, independent of other risk factors.[34] Individuals with OSA are at risk for developing hypertension, and when hypertension is present, it is often resistant to drug therapy.[35] Alleviation of sleep disordered breathing (with nasal continuous positive airway pressure) can improve blood pressure and attenuate some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.[36,37]

TREATMENT

Obstructive Sleep Apnea

In the absence of an underlying cause (e.g., hypothyroidism, acromegaly), alleviation of sleep disordered breathing is the primary goal of treatment. Nonpharmacologic measures are the treatments of choice. There is no drug therapy for OSA. However, medications that worsen sleep should be avoided. Practice parameters for the treatment of OSA have been published by the American Academy of Sleep Medicine.[38]

NONPHARMACOLOGIC THERAPY

Positive Airway Pressure

6 Nasal positive airway pressure (PAP) during sleep is the standard treatment for most patients with OSA. PAP produces a positive pressure column in the upper airway using room air to maintain patency. A flexible tube connects the PAP machine to a mask that covers the nose.

PAP delivery may be continuous (CPAP) or bilevel, providing a reduced applied pressure during expiration. During PSG, the pressure setting is increased (up to 20 cm H_2O) until sleep-disordered breathing is eliminated. Barriers to PAP adherence, such as ill-fitted mask and nasal dryness, can be managed. PAP nonadherence for one night results in a complete reversal of the gains made in daytime alertness.[39] In the clinical setting, poor PAP adherence may impact blood pressure control and management in patients with OSA and hypertension.

Weight Reduction

Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. OSA can itself predispose to weight gain and in obese patients with mild OSA weight loss alone can be effective.[40] Individuals who are morbidly obese and have severe OSA can undergo gastric stapling for weight loss.

Surgery

Surgical therapy (uvulopalatopharyngoplasty) opens the upper airway by removing the tonsils, trimming and reorienting the posterior and anterior tonsillar pillars, and removing the uvula and posterior portion of the palate. This is not a first-line option because it is invasive. In very severe cases tracheostomy can be necessary. This procedure can be indicated for select individuals that are morbidly obese, have severe facial skeletal deformity, experience severe drops in oxygen saturation (e.g., less than 70%), or have significant cardiac arrhythmias associated with their OSA.

Other Therapies

For individuals that experience OSA only during certain sleep positions (e.g., on their back), positional therapies can be effective alone but are usually used in conjunction with PAP therapy. Oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. These therapies should be considered when PAP therapy cannot be tolerated.[41]

PHARMACOLOGIC THERAPY

The most important pharmacologic intervention is the avoidance of all CNS depressants (e.g., alcohol, hypnotics) and drugs that promote weight gain. Weight gain worsens OSA. CNS depressant use is potentially lethal as it reduces the brain's reflex ability to cause a mini-arousal and resume breathing. In addition, certain CNS depressants can relax airway muscles, promoting upper airway collapse. Medications that can cause rhinopharyngeal inflammation and cough as a side effect of therapy (i.e., ACE inhibitor) may also worsen sleep-disordered breathing.

There is no drug therapy for OSA. In clinical trials, serotonergic agents (e.g., fluoxetine, paroxetine), tricyclic antidepressants (TCAs) (i.e., imipramine, protriptyline), respiratory stimulants (aminophylline and theophylline), medroxyprogesterone, and clonidine do not clinically improve severity of OSA. The effects of antihypertensive agents on sleep apnea are inconsistent and are likely not clinically significant.[34,42]

Modafinil (Provigil) is a wake-promoting medication and is FDA approved to improve wakefulness in patients who have residual daytime sleepiness while treated with PAP. Initiation of wake-promoting medications should only be attempted in patients who are using optimal PAP therapy to alleviate sleep-disordered breathing and are free of cardiovascular disease. In patients with concurrent rhinitis, nasal steroids are recommended for use along with PAP therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

Individuals with sleep apnea should be evaluated after 1 to 3 months of treatment for improvement in alertness and daytime symptoms (improvement in memory and decreased irritability) and weight reduction. Individuals experiencing symptoms (e.g., daytime sleepiness, snoring, loss of blood pressure control) despite PAP therapy should have PSG repeated. Symptoms can recur if patients gain weight, requiring a higher pressure setting. Conversely, PAP pressure settings can be decreased if weight loss is achieved. Patient adherence to PAP therapy can be monitored by assessing the built-in compliance meter that measures the hours used at effective pressure.

CENTRAL SLEEP APNEA

CSA causes fragmented sleep and consequent daytime somnolence. However, unlike OSA, arousals from sleep are not required to initiate airflow. During PSG, there is an absence of airflow out of the mouth and nose with no activation of the inspiratory muscles. The prevalence of CSA is not well established and is less than OSA. CSA can be idiopathic but more commonly is caused by underlying autonomic nervous system lesions (e.g., cervical cordotomy), neurologic diseases (e.g., poliomyelitis, encephalitis, and myasthenia gravis), high altitudes, and congestive heart failure.[42] For these reasons, potential underlying causes for CSA should be evaluated and treated. For example, worsening CSA in heart failure patients can signal the need to optimize heart failure therapies.

A few medications have been studied in the setting of high altitude, heart failure, and idiopathic CSA, including acetazolamide, which induces a metabolic acidosis that stimulates respiratory drive, and theophylline, which improves severity of CSA but has no effect on clinical variables.[43,44] PAP therapy with or without supplemental oxygen also improves CSA. However, due to the lack of randomized trials there is no consensus on if and how CSA should be routinely managed, particularly in the setting of heart failure.

NARCOLEPSY

Narcolepsy is a severely debilitating neurologic disease that affects between 0.03% and 0.06% of adult Americans.[45] Despite the debilitating nature of the disease, it can be undiagnosed or misdiagnosed for years. It is equal or somewhat higher in men compared with women, and it has been noted in children and adolescents. However, it is commonly recognized in the second decade of life and increases in severity through the third and fourth decades.[45] Individuals with narcolepsy complain of excessive daytime sleepiness, and in the sleep laboratory, individuals with narcolepsy exhibit impairment of both the onset and the offset of REM and NREM sleep and have arousals and disturbed sleep during the night.

Four characteristic symptoms differentiate narcolepsy from other sleep disorders and are known as the *narcolepsy tetrad*: excessive daytime sleepiness, cataplexy, hypnagogic hallucinations, and sleep paralysis. Cataplexy, a sudden bilateral loss of muscle tone of varying severity and duration without the loss of consciousness, occurs in 70% to 80% of people with narcolepsy.[45] Patients can suffer subtle changes, such as jaw or head slumping, or severe weakness, such as knee buckling or collapsing to the ground. Cataplexy is often precipitated by situations characterized by high emotion (e.g., laughter, anger, excitement). Cataleptic episodes can be brief, lasting seconds, or can last for several minutes. Sleep paralysis is an episodic loss of voluntary muscle tone that occurs when the individual is falling asleep or waking. Individuals are conscious but not able to move or speak. Hallucinations while falling asleep (i.e., hypnagogic) and on awakening (i.e., hypnopompic) are brief, dreamlike experiences that intrude into wakefulness. Nearly 70% of narcoleptics experience these hallucinations. Unfortunately, these symptoms sometimes lead to an incorrect diagnosis of mental illness.[45] Cataplexy, sleep paralysis, and hypnagogic hallucinations can be caused by REM sleep disturbances.[46]

The primary cause of narcolepsy is not known, and causes may include multiple external and internal factors. There can be a genetic component, as 3% of patients have a first-degree relative with the disorder.[46] Onset of disease occurs in adolescence or adulthood, but not at birth, suggesting that environmental influences might play a role. Molecular studies of human leukocyte antigen (HLA) have found a high prevalence of the HLA-DR2 and HLA-DQ6/DQB1 haplotypes in narcoleptics.[47] However, the HLA-DR2 haplotype is also common in the non-narcoleptic population and is not diagnostic.[46] The hypocretin-orexin neurotransmitter system has been implicated and can play a central role in narcolepsy. Neurons containing hypocretin-orexin are found in the lateral hypothalamus and project to various parts of the brain that are thought to regulate sleep. In 75% of narcoleptic patients, hypocretin-orexin is undetectable in cerebrospinal fluid.[47] Because narcoleptic patients have deficiencies in hypocretin-orexin–producing neurons,[48] an autoimmune process may be responsible for the destruction of hypocretin-producing cells.[49,50]

CLINICAL PRESENTATION OF NARCOLEPSY

Symptoms

- Patients may complain of excessive daytime sleepiness and disrupted nighttime sleep; often they have some accompanying REM sleep abnormality, sleep paralysis, cataplexy, and/or hallucinations.

Laboratory Tests

- Although not routinely tested, there is a high incidence of HLA haplotypes DR2 and HLA-DQ6/DQB1 in narcolepsy.

Other Diagnostic Tests

- Narcolepsy is definitively diagnosed using the multiple sleep latency test (nap test). The patient takes four to five naps in a day, and narcolepsy is diagnosed if the patient falls asleep quickly (within less than 5 minutes) and goes into REM sleep in two of those nap periods.

TREATMENT

Narcolepsy

Nonpharmacologic management of narcolepsy includes counseling the patient and family concerning the illness to alleviate misconceptions around the individual's behavior. Good sleep hygiene should be encouraged as well as two or more scheduled daytime naps. Daytime naps lasting 15 minutes each can help the individual with narcolepsy stay refreshed for several hours.

7 Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness (EDS) and cataplexy. Drug therapy for narcolepsy is summarized in Table 81–4.

Modafinil, a racemic compound unrelated to psychostimulants, is a recognized standard treatment for EDS.[51] Armodafinil is the active R-isomer of modafinil and is also FDA approved for treatment of EDS in narcolepsy. The precise mechanism of action of modafinil and armodafinil is not fully understood. Common adverse effects are usually mild and include headache, nausea,

TABLE 81-4 Drugs Used to Treat Narcolepsy[51]

Generic Name	Trade Name	Daily Dosage Range (mg)
Excessive daytime somnolence		
Dextroamphetamine	Dexedrine	5–60
Dextroamphetamine/ Amphetamine salts[a]	Adderall	5–60
Methamphetamine[b]	Desoxyn	5–15
Lisdexamfetamine	Vyvanse	20–70
Methylphenidate	Ritalin	30–80
Modafinil	Provigil	200–400
Armodafinil	Nuvigil	150–250
Sodium oxybate[c]	Xyrem	4.5–9 grams per night
Adjunct agents for cataplexy		
Fluoxetine	Prozac	20–80
Imipramine	Tofranil	50–250
Nortriptyline	Aventyl, Pamelor	50–200
Protriptyline	Vivactil	5–30
Venlafaxine	Effexor	37.5–225
Selegiline	Eldepryl	20–40

[a]Dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate.
[b]Not available in some states.
[c]Also is effective at treating cataplexy.

nervousness, anxiety, and insomnia. The dose of modafinil is between 200 and 400 mg/day, and armodafinil doses are between 150 mg and 250 mg/day.[52] Although both of these agents are effective in treating EDS, they lack efficacy for the treatment of cataplectic symptoms.[53]

EDS can also be treated with stimulants to improve alertness and to increase daytime performance. Dextroamphetamine and methylphenidate also have FDA approval for the treatment of narcolepsy. Methamphetamine has also been used on an off-label basis. Methylphenidate and amphetamines have a fast onset of action and durations of 6 to 10 and 3 to 4 hours, respectively. The dose can range from 5 to 60 mg daily. Many clinicians prescribe both immediate-release and sustained-release stimulants to increase alertness throughout the day. Sustained-release stimulants are prescribed with scheduled administration times, and immediate release stimulants can be taken as needed when the patient requires alertness (e.g., driving, etc.).

Stimulants improve alertness, increase daytime performance, can elevate mood, and prevent sleep. Side effects can include insomnia, hypertension, palpitations, and irritability. Tolerance to long-term stimulant therapy can occur, necessitating dosage increases. Amphetamine use is associated with more likelihood of abuse and tolerance, especially when prescribed in high doses. Lisdexamfetamine is a new amphetamine prodrug rapidly absorbed and converted in the body to dextroamphetamine. Lisdexamfetamine has a longer duration of action and less risk of abuse since it is only active when taken orally.

The most effective treatments for cataplexy are TCAs, venlafaxine, and fluoxetine. The mechanism of antidepressants in relieving cataplexy, hypnagogic hallucinations, and sleep paralysis can be mediated through blockade of serotonin and norepinephrine reuptake in the locus coeruleus and raphe and subsequent suppression of REM sleep.[54] Imipramine, protriptyline, clomipramine, fluoxetine, and nortriptyline are effective in approximately 80% of patients. Selegiline improves hypersomnolence and cataplexy through REM suppression and an increase in REM latency. Methylphenidate and amphetamines alone are usually ineffective for cataplexy.

Sodium oxybate (γ-hydroxybutyrate, Xyrem) improves symptoms of EDS and decreases episodes of sleep paralysis, cataplexy, and hypnagogic hallucinations. Nightly administration of sodium oxybate changes sleep architecture to resemble normal sleep. It increases slow-wave sleep, decreases nighttime awakenings, and increases REM efficiency.[55] Sodium oxybate is available only as a liquid and is taken as two doses; one is taken at bedtime and the second dose is taken 2.5 to 4 hours later. Sodium oxybate is a potent sedative hypnotic and should not be used concomitantly with any other sedating medications. The most common side effects include nausea, somnolence, confusion, dizziness, and incontinence.

EVALUATION OF THERAPEUTIC OUTCOMES

The primary objective of pharmacologic treatment of narcolepsy is to reduce symptoms that adversely impact quality of life. The goal is to produce the fullest possible return of normal function for patients at work, school, home, and in social settings. Patients with narcolepsy should keep a diary of the frequency and severity of cataplexy, sleep paralysis, and sleep hallucinations. Patients should be evaluated regularly during medication titrations and then every 6 to 12 months to assess for adverse drug effects (e.g., sleep disturbances and cardiovascular abnormalities). The health care provider should consider the benefit-to-risk ratio for the individual patient, the cost of medication, the convenience of administration, and the cost of laboratory tests when selecting narcolepsy therapies.[51] One wake-promoting agent may work better than another in an individual patient. Thus, if one agent is not effective at adequate doses, a trial with another agent should be undertaken.

CIRCADIAN RHYTHM DISORDERS

The sleep–wake cycle is under the circadian control of oscillators and can be disrupted by misalignment between an individual's biologic clock and external demands on the sleep cycle. Circadian rhythm sleep disorders usually present with either insomnia or hypersomnia, depending on the individual's performance requirements. Two commonly occurring circadian rhythm sleep disorders are jet lag and shift work sleep problems.

JET LAG

Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Sleep disturbances typically last for 2 to 3 days but can last as long as 7 to 10 days if the time zone changes are greater than 8 hours. Compared with westward travel, eastward travel is associated with a longer duration of jet lag. Jet lag leads to increased incidence of gastrointestinal disturbances and a decrease in alertness and performance.

8 Treatment of jet lag includes nonpharmacologic approaches alone or in combination with drug therapy. Jet lag can be minimized in coast-to-coast travel in the United States if the duration is less than 7 days and the normal sleep–wake cycle is observed. For travel lasting longer than 7 days, jet lag severity can be lessened by 1- to 2-hour adjustments in sleep and wake times prior to departure to the destination time zone. Short-acting benzodiazepine receptor agonists or 0.5 to 5 mg melatonin taken at appropriate target bedtimes for east or west travel reduce jet lag and shorten sleep latency.[56]

SHIFT WORK SLEEP DISORDER

Shift workers comprise approximately 20% of the workforce.[57] Night shift work causes a misalignment in the sleep–wake cycle and circadian rhythm that is associated with a decrease in alertness, performance, and quality of daytime sleep. More than 65% of workers on

rotating shifts complain of insomnia, compared with only 20% who work one shift.[58] Shift workers ultimately are at risk of developing shift work sleep disorder (SWSD). SWSD is a complaint of insomnia or excessive sleepiness that occurs because of working shifts during normal sleep time.[7,57] Shift workers have a higher injury rate, divorce rate, occurrence of on-the-job sleepiness, and incidence of substance use. Shift workers may also be at increased risk of developing peptic ulcers, depression, breast cancer, and sleepiness-related accidents.[57,59,60] Night shift workers are usually in a state of permanent circadian misalignment because of the tendency to revert to conventional sleep schedules on their days off.[58]

Treatment for shift work sleep problems includes optimizing sleep hygiene, extending daytime sleep by sleeping in the afternoon, scheduling a 2- to 3-hour nap on days off from work, or switching to a day shift job. Short-acting benzodiazepine receptor agonists can consolidate sleep during day sleep periods and reduce lost sleep time. Modafinil is FDA approved to improve wakefulness in patients with excessive daytime sleepiness associated with SWSD. Scheduled exposure to bright lights at night and darkness in the daytime improves adaptation to night work and daytime sleep.[58] Melatonin has also been used successfully.

RESTLESS LEGS SYNDROME

Restless legs syndrome (RLS), or Ekbom syndrome, is characterized by paresthesias that are usually felt deep in the calf muscles but can also appear in the thighs and arms with the urge to keep limbs in motion. RLS occurs in both males and females, and it occurs more frequently in the elderly. It has been associated with chronic kidney disease, iron deficiency anemia, and pregnancy. Caffeine, stress, alcohol, and fatigue can worsen symptoms. Recent data suggest that RLS can be caused by iron deficiency in the substantia nigra in the CNS.[60] The diagnosis of RLS is based on patient- or partner-reported symptoms and specific diagnostic criteria. Criteria required to diagnose RLS include (1) an urge to move the limbs that is usually associated with uncomfortable and unpleasant sensations, (2) symptoms that begin or worsen during rest or inactivity, (3) symptoms that are exclusively present or worse in the evening or night, and (4) symptoms that are temporarily relieved by movement.[61] The discomfort returns when the person tries to sleep, resulting in insomnia.

9 Dopamine agonists are effective for RLS and have replaced levodopa as first-line therapy.[62] Ropinirole and pramipexole are FDA approved for RLS.[62] Lower doses of dopamine agonists are used when treating RLS compared with Parkinson disease. Providers should caution patients that compulsive behaviors (e.g., gambling, shopping, eating, etc.) may emerge during therapy with dopamine agonists. Levodopa therapy is associated with a high incidence of symptom augmentation and, because of a short half-life, might not provide relief over the entire night. Augmentation is a worsening in symptom severity, increase in symptom distribution, or emergence of symptoms earlier in the evening. Sedative hypnotic agents can be effective in patients who have frequent awakenings from their RLS symptoms. Clonazepam at doses ranging from 0.5 mg to 2 mg has been most frequently studied; however, patients frequently experience carryover sedation because of its long duration of action. Shorter half-life sedative hypnotics (e.g., zolpidem, zaleplon, triazolam) can improve sleep and reduce daytime sleepiness without carryover sedation. Opiates such as methadone 5 to 20 mg, codeine 30 to 120 mg, and oxycodone 2.5 mg are very effective for patients with painful RLS. The potential for tolerance and dependence on opiate therapy should be considered. Gabapentin 300 to 900 mg near bedtime can also be considered for those with paresthetic or painful RLS symptoms.[63] Iron studies should be completed in patients with RLS and iron supplementation initiated in those that are iron deficient. In patients with ferritin concentrations less than 50 to 75 mcg/L (ng/mL), iron supplementation improves RLS symptoms.[64] Patients with RLS or periodic limb movements of sleep should be evaluated regularly to monitor for excessive daytime somnolence, tolerance, efficacy, and adverse effects of the medication.

PERIODIC LEG MOVEMENTS OF SLEEP

RLS patients commonly have periodic limb movements during sleep, while approximately one-third of patients with PLMS have RLS.[62] PLMS are stereotypic, repetitive, periodic movements of the legs that occur during sleep every 20 to 40 seconds and last 10 minutes to several hours.[62] The movements usually involve the big toe, but the ankle, knee, and hip can also flex. They can be terminated by a violent kick or other body movement. Often patients will be unaware of these movements and only recognize consequent insufficient sleep and morning leg cramps. A bed partner can describe PLMS. PLMS is diagnosed in the sleep laboratory using electromyogram recordings. Bursts of muscle activity lasting 0.5 to 5 seconds that recur at least 40 times within 8 hours of sleep are diagnostic.[62]

PLMS can occur with RLS or alone because of systemic disease (e.g., renal failure) or drug therapy.[65] TCAs, SSRIs, dopaminergic antagonists, xanthines, nicotine, alcohol, and caffeine can all worsen PLMS. The treatment approach for PLMS is similar to that of RLS. If PLMS do not cause disruptions for the patient or bed partner or daytime symptoms, they might not require treatment. Symptomatic or problematic PLMS should be treated with dopaminergic medications to suppress limb movements or sedative hypnotics to reduce awakenings and consolidate sleep.

PARASOMNIAS

Parasomnias are abnormal behavior or physiologic events that either occur during sleep or are exaggerated by sleep. Many of these disorders are considered to be disorders of partial arousal from various sleep stages. Parasomnias can be categorized as disorders of arousal (sleepwalking, sleep terrors), sleep–wake transition disorders (sleeptalking), rhythmic movement disorder, REM parasomnias (REM-behavior disorder, nightmares), and miscellaneous parasomnias (enuresis, bruxism). Sleepwalking, sleep terrors, and sleeptalking predominantly occur during NREM sleep, whereas others (REM-behavior disorder) occur during REM sleep.

Sleepwalking and sleep terrors are found normally in children between the ages of 4 and 12 years and usually resolve in adolescence. These disorders are associated with psychopathology only if they persist into adulthood.[66] Sleep terrors can begin in adults between the ages of 20 and 30 years. Onset of sleepwalking in adults without a childhood history of sleepwalking should prompt a search for a neurologic or substance-use condition.[66] Sleepwalking and sleep terror disorder involve intrusions of wakefulness into NREM sleep during the first third of the night. In sleepwalking, individuals become ambulatory, are difficult to awaken, and are amnestic for the event. Sleep terrors involve intense fear and autonomic arousal. Individuals are difficult to awaken, inconsolable, and amnestic for the event.[66] Patients with REM-behavior disorder act out their dreams, often in a violent manner, and are at risk for injury.

Treatment of sleepwalking involves protecting the individual from harm by putting safety latches on doors and windows, removing hazardous objects from bedrooms, and covering glass doors with heavy curtains. In adult patients, benzodiazepines, SSRIs, or TCAs can be beneficial therapies for sleepwalking or other

NREM disorders of arousal.[67] Benzodiazepines can also be helpful in curtailing sleep terrors in adults.[66] Nightmares are anxiety-provoking dreams characterized by vivid recall. Treatment is directed at reducing stress, anxiety, and sleep deprivation. In extreme cases, low-dose benzodiazepines can be indicated. Clonazepam is the treatment of choice for REM behavior disorder. Melatonin (3–12 mg at bedtime) can also be an effective therapy for REM behavior disorder.[68]

PHARMACOECONOMIC CONSIDERATIONS

Despite the prevalence of sleep disorders, most cases go undiagnosed and untreated. In the United States, the direct and indirect costs of insomnia alone add over $100 billion to the national health care bill each year.[1,69] Improvements in recognition and treatment can decrease the economic burden and prevent progression to both medical and psychiatric disorders.

Quality of life can be improved by appropriate treatment. For example, treatment of OSA with PAP improves the number of years of good health by 5.5 quality-adjusted life years. Hypnotic therapy has also been found to markedly improve both the disorder and quality of life in shift workers.[70]

CONCLUSIONS

Disturbances of sleep affect approximately one third of the population. Patients with sleep disorders should be accurately identified and diagnosed. Patients can have one or more concomitant sleep disorders. Unrecognized and poorly treated sleep disorders can worsen severity of and ability to effectively treat underlying systemic diseases. Effective management of sleep disorders involves combined nonpharmacologic and pharmacologic treatment.

ABBREVIATIONS

CPAP: continuous positive airway pressure

CNS: central nervous system

CSA: central sleep apnea

DSM-IV-TR: Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision

EDS: excessive daytime sleepiness

EEG: electroencephalogram

FDA: Food and Drug Administration

GABA: γ-aminobutyric acid

HLA: human leukocyte antigen

NREM: nonrapid eye movement (sleep)

OSA: obstructive sleep apnea

PAP: positive airway pressure

PLMS: periodic limb movement during sleep

PSG: polysomnography

RDI: respiratory disturbance index

REM: rapid eye movement (sleep)

RLS: restless legs syndrome

SSRI: selective serotonin reuptake inhibitor

SWSD: shift work sleep disorder

TCA: tricyclic antidepressant

CHAPTER 82

Disorders Associated with Intellectual Disabilities

NANCY BRAHM, JERRY MCKEE, AND DOUGLAS STEWART

KEY CONCEPTS

1. Persons diagnosed with Down syndrome can be at increased risk for medical and psychiatric comorbidities.
2. Develop treatment plans for persons with autism to increase social interactions, improve verbal and nonverbal communication, and minimize the occurrence or impact of ritualistic, repetitive behaviors and other related mood and behavioral problems (e.g., overactivity, irritability, self-injury).
3. Differentiate between purported treatments for autism and effective treatments supported by evidence-based pharmacotherapy principles.
4. Develop a structured teaching approach focusing on increasing social communication and integration with peers in persons with autism.
5. Develop a psychopharmacologic treatment plan including monitoring of objective and measurable medication-responsive target behaviors and assessment of potential adverse effects.
6. Differentiate between the four stages of Rett syndrome associated with developmental regression.

Intellectual disabilities (ID) can be identified in childhood or adolescence. Current criteria for a diagnosis are based on deficiencies in intellectual and adaptive functioning with an onset prior to 18 years of age.[1] This diagnosis is made regardless of the presence or absence of concomitant medical or psychiatric disorders. In the case of mild ID, deficiencies may not be initially apparent. Problems can be noted when the chronologic age of the child and the developmental milestones achieved by peers with similar backgrounds, cultures, and socioeconomic and psychosocial settings differ significantly.[1] These gaps widen as the individual ages.

Adaptive functioning deficits pose a number of challenges in treating those with an ID. This population can be 4 to 5 times more likely to experience mental health problems compared with the general population.[2] Until recently, little attention was given to this population and the need to evaluate them for psychiatric illnesses, leading to under-recognition of psychopathology. This oversight is a function of several factors, including limited population-specific training for clinicians and a general lack of clinical experience with patients with ID during training.[2] Additional barriers are individual deficits in expressive and receptive language, a lack of mental health screening initiatives, and limited diagnostic testing instruments specific to this population.[2]

Those with ID often have few social interactions and limited integration into the community. Stimulation and interaction with peers typically shapes behaviors in the general population. A different set of coping skills can develop in their absence. Self-talk is an example of a coping mechanism that can be misinterpreted for psychosis. Another potential problem for the clinician assessing persons with an ID is a significant gap between receptive and expressive language skills. If not readily recognized, intellectual capabilities can be overestimated, expectations falsely elevated, and coping skills can be inadequate, leading to anxiety-induced decompensation.[2]

SECTION 8
ENDOCRINOLOGIC DISORDERS

CHAPTER 83

Diabetes Mellitus

CURTIS L. TRIPLITT AND CHARLES A. REASNER

KEY CONCEPTS

1. Diabetes mellitus (DM) is a group of metabolic disorders of fat, carbohydrate, and protein metabolism that results from defects in insulin secretion, insulin action (sensitivity), or both.
2. The incidence of type 2 DM is increasing. This has been attributed in part to a Western-style diet, increasing obesity, sedentary lifestyle, and an increasing minority population.
3. The two major classifications of DM are type 1 (insulin deficient) and type 2 (combined insulin resistance and relative deficiency in insulin secretion). They differ in clinical presentation, onset, etiology, and progression of disease. Both are associated with microvascular and macrovascular disease complications.
4. Diagnosis of diabetes is made by four criteria: fasting plasma glucose ≥126 mg/dL; a 2-hour value from a 75-g oral glucose tolerance test ≥200 mg/dL; a casual plasma glucose level of ≥200 mg/dL with symptoms of diabetes; or a HbA_{1c} ≥6.5%. The diagnosis should be confirmed by repeat testing if obvious hyperglycemia is not present.
5. Goals of therapy in DM are directed toward attaining normoglycemia (or appropriate glycemic control based on the patient's comorbidities), reducing the onset and progression of retinopathy, nephropathy, and neuropathy complications, intensive therapy for associated cardiovascular risk factors, and improving quality and quantity of life.
6. Metformin should be included in the therapy for all type 2 DM patients, if tolerated and not contraindicated, as it is the only oral antihyperglycemic medication proven to reduce the risk of total mortality, according to the United Kingdom Prospective Diabetes Study (UKPDS).
7. Intensive glycemic control is paramount for reduction of microvascular complications (neuropathy, retinopathy, and nephropathy) as evidenced by the Diabetes Control and Complications Trial (DCCT) in type 1 DM and the UKPDS in type 2 DM. The UKPDS also reported that control of hypertension in patients with diabetes will not only reduce the risk of retinopathy and nephropathy, but also reduce cardiovascular risk.
8. Short-term (3–5 years), intensive glycemic control does not lower the risk of macrovascular events as reported by the Action in Diabetes and Vascular Disease, Action to Control Cardiovascular Risk in Diabetes, and Veterans Administration Diabetes Trial trials. Microvascular event reduction may be sustained, and macrovascular events reduced by improved early glycemic control, as evidenced by the UKPDS and DCCT follow-up studies. Significant reductions in macrovascular risk may take 15 to 20 years. This sustained reduction in microvascular risk and new reduction in macrovascular risk has been coined metabolic memory.
9. Knowledge of the patient's quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations, and pharmacology of oral and injected antihyperglycemic agents are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.
10. Type 1 DM treatment necessitates insulin therapy. Currently, the basal-bolus insulin therapy or pump therapy in motivated individuals often leads to successful glycemic outcomes. Basal-bolus therapy includes a basal insulin for fasting and postabsorptive control, and rapid acting bolus insulin for mealtime coverage. Addition of mealtime pramlintide in patients with uncontrolled or erratic postprandial glycemia may be warranted.
11. Type 2 DM treatment often necessitates use of multiple therapeutic agents (combination therapy), including oral and/or injected antihyperglycemics and insulin to obtain glycemic goals due to the persistant reduction in β-cell function over time.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Slowing, but not arresting, β-cell failure has been shown with thiazolidinediones and the GLP-1 agonist class of medications.

12 Aggressive management of cardiovascular disease risk factors in type 2 DM is necessary to reduce the risk for adverse cardiovascular events or death. Smoking cessation, use of antiplatelet therapy as a secondary prevention strategy and in select primary prevention situations, aggressive management of dyslipidemia: primary goal to lower low-density lipoprotein-cholesterol (<100 mg/dL) and secondarily to raise high-density lipoprotein-cholesterol to ≥40 mg/dL, and treatment of hypertension (again often requiring multiple drugs) to <130/80 mm Hg are vital.

13 Prevention strategies for type 1 DM have been unsuccessful. Prevention strategies for type 2 DM are established. Lifestyle changes, dietary restriction of fat, aerobic exercise for 30 minutes 5 times a week, and weight loss, form the backbone of successful prevention. No medication is currently FDA approved for prevention of diabetes, though several, including metformin, acarbose, pioglitazone, and rosiglitazone, have clinical trials demonstrating a delay of diabetes onset.

14 Patient education and ability to demonstrate self-care and adherence to therapeutic lifestyle and pharmacologic interventions are crucial to successful outcomes. Multidisciplinary teams of healthcare professionals including physicians (primary care, endocrinologists, ophthalmologists, and vascular surgeons), podiatrists, dietitians, nurses, pharmacists, social workers, behavioral health specialists, and certified diabetes educators are needed, as appropriate, to optimize these outcomes in persons with diabetes mellitus.

1 Diabetes mellitus (DM) is a group of metabolic disorders characterized by hyperglycemia. It is associated with abnormalities in carbohydrate, fat, and protein metabolism and results in chronic complications including microvascular, macrovascular, and neuropathic disorders. Nearly 24 million Americans have DM, with as many as one-fourth of these patients being undiagnosed, and an additional 57 million potentially having pre-diabetes.[1] The economic burden of DM approximated $174 billion in 2007, including direct medical and treatment costs as well as indirect costs attributed to disability and mortality.[1] DM is the leading cause of blindness in adults aged 20 to 74 years, and the leading contributor to development of endstage renal disease. It also accounts for approximately 71,000 lower extremity amputations annually.[1] Finally, a cardiovascular event is responsible for two-thirds of deaths in individuals with type 2 DM.[1]

Optimal management of the patient with DM will reduce or prevent complications, and improve quality of life. Research and drug development efforts over the past several decades have provided valuable information that applies directly to improving outcomes in patients with DM and have expanded the therapeutic armamentarium. Additionally, interventions in an attempt to prevent complications and the onset of diabetes have been reported for type 1 and 2 DM.

EPIDEMIOLOGY

Type 1 DM is an autoimmune disorder developing in childhood or early adulthood, although some latent forms do occur. Type 1 DM idiopathic is a nonimmune form of diabetes frequently seen in minorities, especially Africans and Asians, with intermittent insulin requirements.[2] Type 1 DM accounts for 5% to 10% of all cases of DM and is likely initiated by the exposure of a genetically susceptible individual to an environmental agent.[3] Candidate genes and environmental factors are reportedly prevalent in the general population, but development of β-cell autoimmunity occurs in less than 10% of the genetically susceptible population and progresses to type 1 DM in less than 1% of the population.[4] The prevalence of β-cell autoimmunity appears proportional to the incidence of type 1 DM in various populations. For instance, the countries of Sweden, Sardinia, and Finland have the highest prevalence of islet cell antibody (3%–4.5%) and are associated with the highest incidence of type 1 DM; 22 to 35 per 100,000.[5] The prevalence of type 1 DM has been increasing over the last hundred years, but the cause of the increase is not fully understood.[6]

Markers of autoimmunity have been detected in 14% to 33% of persons with type 2 DM in some populations and manifest with early failure of oral agents and insulin dependence. This type of DM has also been referred to as latent autoimmune diabetes in adults (LADA).[5]

Maturity onset diabetes of youth (MODY), which can be due to one of at least six genetic defects, and endocrine disorders such as acromegaly and Cushing syndrome, can be secondary causes of DM.[7] These unusual etiologies, however, only account for 1% to 2% of the total cases of type 2 DM. See the section on other forms of diabetes mellitus later in this chapter for further discussion.

2 The prevalence of type 2 DM is increasing. Type 2 DM accounts for as much as 90% of all cases of DM, and overall the prevalence of type 2 DM in the United States is about 10.7% in persons age 20 or older. Additionally, there is likely one person undiagnosed for every four persons currently diagnosed with the disease.[1] Multiple risk factors for the development of type 2 DM have been identified, including family history (i.e., parents or siblings with diabetes); obesity (i.e., ≥20% over ideal body weight, or body mass index [BMI] ≥25 kg/m^2); habitual physical inactivity; race or ethnicity (see list below); previously identified impaired glucose tolerance, impaired fasting glucose, or HbA_{1c} 5.7%–6.4% (see diagnosis of diabetes section); hypertension (≥140/90 mm Hg in adults); high-density lipoprotein (HDL) cholesterol ≤35 mg/dL and/or a triglyceride level ≥250 mg/dL; history of gestational diabetes mellitus (GDM) (see classification of diabetes section) or delivery of a baby weighing >9 pounds; history of vascular disease; presence of acanthosis nigricans; and polycystic ovary disease.[8] The prevalence of type 2 DM increases with age, it is more common in women than in men in the United States, and varies widely among various racial and ethnic populations, being especially increased in some groups of Native Americans, Hispanic American, Asian American, African American, and Pacific Island people[9] (Fig. 83–1). While the prevalence of type 2 DM increases with age (Fig. 83–2)[9], the disorder is increasingly being recognized in adolescence.

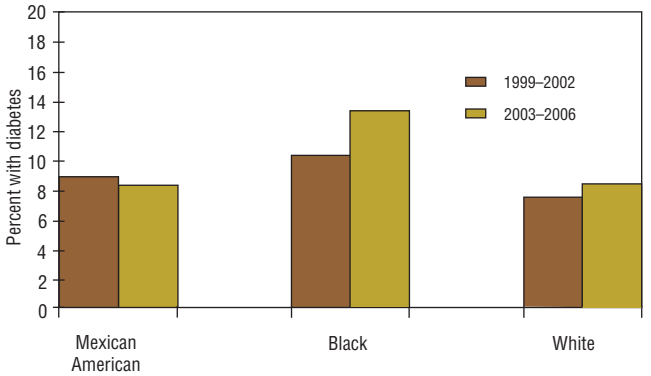

FIGURE 83-1. NHANES Prevalence of Diabetes by Race among Adults ≥20 Years of Age: United States, 1999–2002 and 2003–2006. *(Adapted from Cheung BMY, et al. Diabetes Prevalence and Therapeutic Target Achievement in the United States, 1999 to 2006. Am J Med 2009;122:443–453.)*

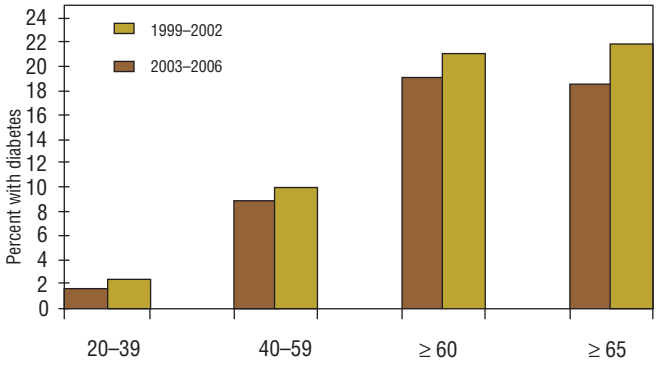

FIGURE 83-2. NHANES Prevalence of Diabetes by Age among Adults ≥20 Years of Age: United States, 1999–2002 and 2003–2006. *(Adapted from Cheung BMY, et al. Diabetes Prevalence and Therapeutic Target Achievement in the United States, 1999 to 2006. Am J Med 2009;122:443–453.)*

Much of the rise in adolescent type 2 DM is related to an increase in adiposity and sedentary lifestyle, in addition to an inheritable predisposition.[10] Most cases of type 2 DM do not have a well-known cause; therefore, it is uncertain whether it represents a few or many independent disorders manifesting as hyperglycemia.[11]

Gestational diabetes mellitus complicates roughly 7% of all pregnancies in the United States.[12] Most women will return to normoglycemia postpartum, but 30% to 50% will develop type 2 DM or glucose intolerance later in life.

PATHOGENESIS, DIAGNOSIS, AND CLASSIFICATION

CLASSIFICATION OF DIABETES

Diabetes is a metabolic disorder characterized by resistance to the action of insulin, insufficient insulin secretion, or both.[13] The clinical manifestation of these disorders is hyperglycemia. The vast majority of diabetic patients are classified into one of two broad categories: type 1 diabetes caused by an absolute deficiency of insulin, or type 2 diabetes defined by the presence of insulin resistance with an inadequate compensatory increase in insulin secretion. Women who develop diabetes due to the stress of pregnancy are classified as having gestational diabetes. Finally, uncommon types of diabetes caused by infections, drugs, endocrinopathies, pancreatic destruction, and known genetic defects are classified separately (Table 83–1).

TABLE 83-1 Etiologic Classification of Diabetes Mellitus

1. Type 1 diabetes[a] (β-cell destruction, usually leading to absolute insulin deficiency)
- Immune mediated
- Idiopathic

2. Type 2 diabetes[a] (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)

3. Other specific types
- Genetic defects of β-cell function
  - Chromosome 20q, HNF-4α (MODY1)
  - Chromosome 7p, glucokinase (MODY2)
  - Chromosome 12q, HNF-1β (MODY3)
  - Chromosome 13q, insulin promoter factor (MODY4)
  - Chromosome 17q, HNF-1β (MODY5)
  - Chromosome 2q, neurogenic differentiation 1/β-cell e-box transactivator 2 (MODY 6)
  - Mitochondrial DNA
  - Others
- Genetic defects in insulin action
  - Type A insulin resistance
  - Leprechaunism
  - Rabson-Mendenhall syndrome
  - Lipoatrophic diabetes
  - Others
- Diseases of the exocrine pancreas
  - Pancreatitis
  - Trauma/pancreatectomy
  - Neoplasia
  - Cystic fibrosis
  - Hemochromatosis
  - Fibrocalculous pancreatopathy
  - Others
- Endocrinopathies
  - Acromegaly
  - Cushing syndrome
  - Glucagonoma
  - Pheochromocytoma
  - Hyperthyroidism
  - Somatostatinoma
  - Aldosteronoma
  - Others
- Drug or chemical induced
  - Vacor (pyriminil)
  - Pentamidine
  - Nicotinic acid
  - Glucocorticoids
  - Thyroid hormone
  - Diazoxide
  - β-Adrenergic agonists
  - Thiazides
  - Phenytoin
  - α-Interferon
  - Others
- Infections
  - Congenital rubella
  - Cytomegalovirus
  - Others
- Uncommon forms of immune-mediated diabetes
  - "Stiff-man" syndrome
  - Anti-insulin receptor antibodies
  - Others
- Other genetic syndromes sometimes associated with diabetes
  - Down syndrome
  - Klinefelter syndrome
  - Turner syndrome
  - Wolfram syndrome
  - Friedreich ataxia
  - Huntington chorea
  - Laurence-Moon-Biedel syndrome
  - Myotonic dystrophy
  - Porphyria
  - Prader-Willi syndrome
  - Others

4. Gestational diabetes mellitus (GDM)

[a]Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not in itself classify the patient.
From Diabetes Care, Vol. 20, 1997; 1183-1197. Reproduced by permission of The American Diabetes Association.[13]

Type 1 Diabetes

3 This form of diabetes results from autoimmune destruction of the β cells of the pancreas. Markers of immune destruction of the β cell are present at the time of diagnosis in 90% of individuals and include islet cell antibodies, antibodies to glutamic acid decarboxylase, and antibodies to insulin. While this form of diabetes usually occurs in children and adolescents, it can occur at any age. Younger individuals typically have a rapid rate of β-cell destruction and present with ketoacidosis, while adults often maintain sufficient insulin secretion to prevent ketoacidosis for many years, which is often referred to as latent autoimmune diabetes in adults.[5]

Type 2 Diabetes

3 This form of diabetes is characterized by insulin resistance and a relative lack of insulin secretion, with progressively lower insulin secretion over time. Most individuals with type 2 diabetes exhibit abdominal obesity which itself causes insulin resistance. In addition, hypertension, dyslipidemia (high triglyceride levels and low HDL-cholesterol levels), and elevated inhibitor plasminogen activator-1 (PAI-1) levels, which contributes to a hypercoagulable state, are often present in these individuals. This clustering of abnormalities is referred to as the "insulin resistance syndrome" or the "metabolic syndrome." Because of these abnormalities, patients with type 2 diabetes are at increased risk of developing macrovascular complications. Type 2 diabetes has a strong genetic predisposition and is more common in all ethnic groups other than those of European ancestry. At this point the genetic cause of most cases of type 2 diabetes is not well defined.[14]

Gestational Diabetes Mellitus

Gestational diabetes mellitus is defined as glucose intolerance which is first recognized during pregnancy. Clinical detection is important, as therapy will reduce perinatal morbidity and mortality.

Other Specific Types of Diabetes

Genetic Defects Maturity onset diabetes of youth is characterized by impaired insulin secretion in respond to a glucose stimulus with minimal or no insulin resistance. Patients typically exhibit mild hyperglycemia at an early age, but diagnosis may be delayed, depending on the severity of presentation. The disease is inherited in an autosomal dominant pattern with at least six different loci identified to date (MODY 2 and 3 are most common). The production of mutant insulin molecules has been identified in a few families and results in mild glucose intolerance.

Several genetic mutations have been described in the insulin receptor and are associated with insulin resistance. Type A insulin resistance refers to the clinical syndrome of acanthosis nigricans, virilization in women, polycystic ovaries, and hyperinsulinemia. In contrast, type B insulin resistance is due to autoantibodies to the insulin receptor. Leprechaunism is a pediatric syndrome with specific facial features and severe insulin resistance due to a defect in the insulin-receptor gene. Lipoatrophic diabetes probably results from postreceptor defects in insulin signaling.

SCREENING

Type 1 Diabetes Mellitus

There is still a low prevalence of type 1 DM in the general population and due to the acuteness of symptoms in most individuals, screening for type 1 DM is not recommended.[8] Screening for islet autoantibody status in high-risk family members may be appropriate, but is recommended to be done in the context of ongoing clinical trials for the prevention of type 1 DM.

Type 2 Diabetes Mellitus

Based on expert opinion, and not uniformly accepted by all guidance organizations, the American Diabetes Association (ADA) recommends screening for type 2 DM at any age in individuals with who are overweight (BMI ≥25 kg/m^2) and have at least one other risk factor. The recommended screening test is the fasting plasma glucose, HbA_{1c}, or 2-hour oral glucose tolerance test (OGTT). Adults without risk factors should be screened starting at age 45 years, as age itself is a risk factor for type 2 DM. The optimal time between screenings is not known. The index of suspicion for the presence of diabetes should guide the clinician.

Children and Adolescents

Despite a lack of clinical evidence to support widespread testing of children for type 2 DM, it is clear that more children and adolescents are developing type 2 DM. The ADA, by expert opinion, recommends that overweight (defined as BMI >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal [50th percentile] for height) youths with at least two of the following risk factors: a family history of type 2 diabetes in first- and second-degree relatives; Native Americans, African Americans, Hispanic Americans, and Asians/South Pacific Islanders; those with signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome, or small for gestational age birthweight); or maternal history of diabetes or gestational diabetes mellitus during the child's gestation be screened. Screening should be done every 3 years starting at 10 years of age or at the onset of puberty if it occurs at a younger age.[8]

Gestational Diabetes

Risk assessment for GDM should occur at the first prenatal visit. Women at high risk (positive family history, history of GDM or delivery of large-for-gestational–age infant, marked obesity, diagnosis of polycystic ovary syndrome, or member of a high-risk ethnic group) should be screened as soon as feasible. If the initial screening is negative they should undergo retesting at 24 to 28 weeks' gestation, as should all other pregnant women with the possible exception of low-risk primagravidas. Evaluation for GDM can be done in one of two ways. The one-step approach involves a 3-hour, 100 g-OGTT and may be cost-effective in high-risk patient populations. The two-step approach uses a screening test to measure plasma or serum glucose concentration 1 hour after a 50-g oral glucose load (glucose challenge test [GCT]), followed by a diagnostic 3-hour OGTT on the subset of women exceeding a glucose threshold of either ≥140 mg/dL (80% sensitive) or ≥130 mg/dL (90% sensitive). The diagnosis of GDM is based on the 100-g OGTT and at least two measured glucose values meeting or exceeding criteria. Criteria for diagnosis of GDM based on the OGTT are summarized in Table 83–2.

TABLE 83-2 Diagnosis of Gestational Diabetes Mellitus with a 100-g Glucose Load

100-g Glucose load

Time	Plasma Glucose
Fasting	≥95 mg/dL (5.3 mmol/L)
1 hour	≥180 mg/dL (10.0 mmol/L)
2 hours	≥155 mg/dL (8.6 mmol/L)
3 hours	≥140 mg/dL (7.8 mmol/L)

Two or more values must be met or exceeded for a diagnosis of diabetes to be made. The test should be done in the morning after an 8- to 14-hour fast.

DIAGNOSIS OF DIABETES

4 The diagnosis of diabetes requires the identification of a glycemic cut point, which discriminates normals from diabetic patients (Table 83–3). The cut points reflect the level of glucose above which microvascular complications have been shown to increase. Cross-sectional studies from Egypt, in Pima Indians, and in a representative sample from the United States have shown a consistent increase in the risk of developing retinopathy at a fasting glucose level above 99 to 116 mg/dL (5.5–6.4 mmol/L), at a 2-hour postprandial level above 125 to 185 mg/dL (6.9–10.3 mmol/L), and a hemoglobin A_{1c} (HbA_{1c}) above 5.9 to 6.0% (Fig. 83–3).[13,15,16]

TABLE 83-3 Criteria for the Diagnosis of Diabetes Mellitus[a]

1. HbA_{1c} ≥6.5%. The test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the DCCT assay.[a]
2. Fasting plasma glucose ≥126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.[a]
3. 2-hour plasma glucose ≥200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g andydrous glucose dissolved in water.[a]
4. In a patient with classic symptoms of hyperglycemica or hyperglycemic crisis, a random plasma glucose concentration ≥200 mg/dL (11.1 mmol/L).

[a]In the absence of unequivocal hyperglycemia, criteria 1 to 3 should be confirmed by repeat testing.

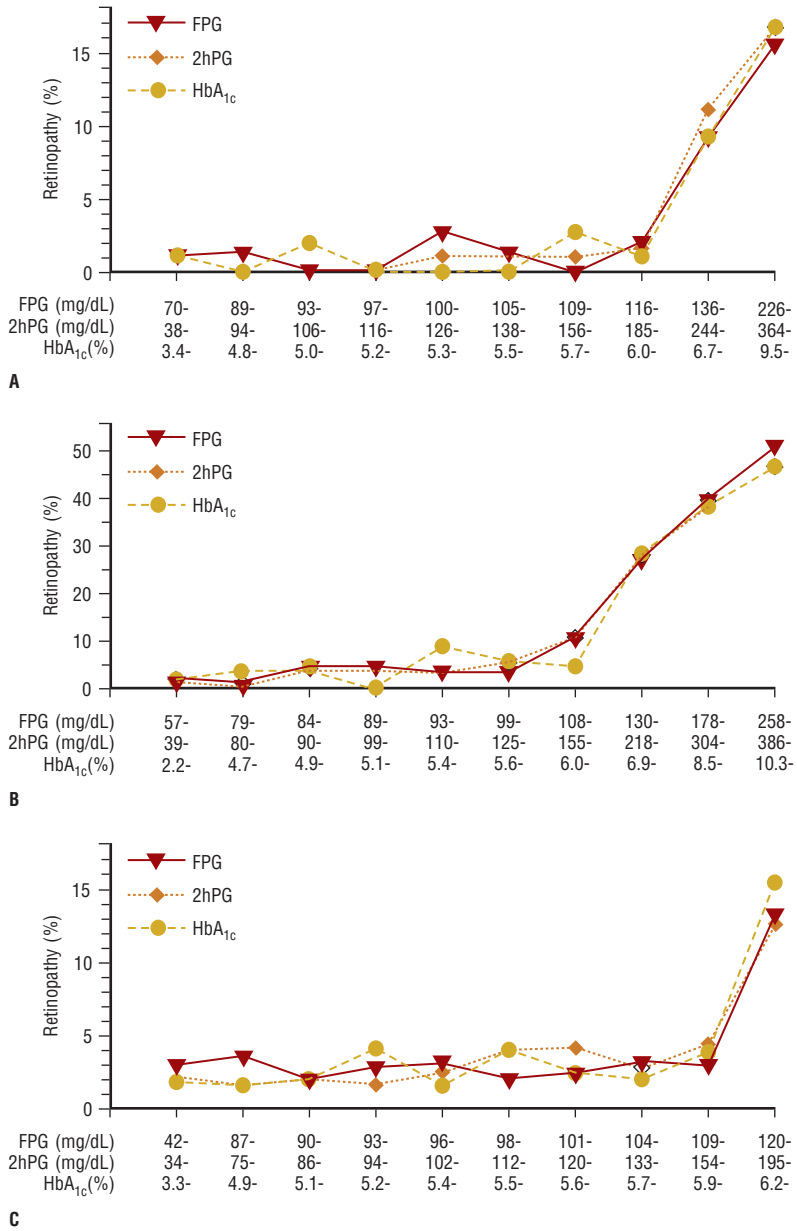

FIGURE 83-3. Prevalence of retinopathy by deciles of the distribution of fasting plasma glucose (FPG), 2-hour postprandial glucose (2-h PG), and hemoglobin A_{1c} (HbA_{1c}) in *(A)* Pima Indians, *(B)* Egyptians, and *(C)* in 40- to 74-year old participants in National Health and Nutrition Examination Survey (NHANES) III.[8] The *x*-axis labels indicate the lower limit of each decile group. Note that these deciles and the prevalence rates of retinopathy differ considerably among the studies, especially the Egyptian study, in which diabetic subjects were oversampled. Retinopathy was ascertained by different methods in each study; therefore, the absolute prevalence rates are not comparable between studies, but their relationships with FPG, 2-h PG, and HbA_{1c} are very similar within each population.

HbA_{1c} ≥6.5% has been newly added as a fourth diagnostic criterion for diabetes mellitus. The HbA_{1c} was not recommended in the past due to many nonstandardized assays. Most laboratories now use a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the DCCT assay, which allows for cross-application of their results. If standardized, the HbA_{1c} is logical for the diagnosis of diabetes as it measures glycemic exposure over the past 2 to 3 months, in contrast to a single-day, single-point glucose evaluation. In addition, patients do not have to be fasting. A HbA_{1c} of 6.0% to 6.4% denotes a 10-fold increase in risk of diabetes, yet does not consistently identify patients with impaired fasting glucose or impaired glucose tolerance. In addition, there are slight race differences in normal HbA_{1c} levels, so 6.5% was chosen to minimize these limitations. The ADA continues to recommend three other glucose criteria for the diagnosis of diabetes mellitus in nonpregnant adults (Table 83–3). It should be noted that a continuum of risk exists as glycemia increases, and sound clinical judgment as to the future risk of diabetes in the context of HbA_{1c} and plasma glucose levels should be applied. If the patient has obvious hyperglycemia and diabetes, reconfirmation is no longer needed.

In addition, as shown in Table 83–4, the ADA added a HbA_{1c} value of 5.7% to 6.4% to define an increased risk for diabetes. The HbA_{1c} lower limit of 5.7% was chosen due to its good specificity, though it has a low sensitivity, to identify patients at increased risk for diabetes. Impaired fasting glucose (IFG) continues to be defined as a plasma glucose of at least 100 mg/dL (5.6 mmol/L) but less than 126 mg/dL (7.0 mmol/L). Impaired glucose tolerance (IGT), is defined as a 2-hour glucose value ≥140 mg/dL (7.8 mmol/L), but less than 200 mg/dL (11.0 mmol/L) during a 75 g-OGTT.

Serial measurements, at clinician-defined intervals, can help to identify patients moving toward diabetes, and those who are stable. Patients who have even minor increases in glucose or HbA_{1c} values over time should be followed closely. Pathophysiologically, the fasting and postprandial glucose levels do not measure the same physiologic processes. The fasting glucose reflects hepatic glucose production, which is mainly determined by the insulin secretory capacity and glucagon released by the pancreas. The postprandial glucose reflects uptake of glucose in peripheral tissues (muscle and fat) and depends on insulin sensitivity of these tissues. Also, the HbA_{1c} measurement can be affected by several hemoglobinopathies, which necessitates the use of one of the plasma glucose criterion in these individuals.

TABLE 83-4 Categorization of Glucose Status

Fasting plasma glucose (FPG)
Normal
- FPG <100 mg/dL (5.6 mmol/L)

Impaired fasting glucose (IFG)
- 100–125 mg/dL (5.6–6.9 mmol/L)

Diabetes mellitus[a]
- FPG ≥126 mg/dL (7.0 mmol/L)

2-Hour postload plasma glucose (oral glucose tolerance test)
Normal
- Postload glucose <140 mg/dL (7.8 mmol/L)

Impaired glucose tolerance (IGT)
- 2-hour postload glucose 140–199 mg/dL (7.8–11.1 mmol/L)

Diabetes mellitus[a]
- 2-hour postload glucose ≥200 mg/dL (11.1 mmol/L)

HbA_{1c}
Normal
- HbA_{1c} <5.7%

Increased risk of diabetes mellitus
- HbA_{1c} 5.7% to 6.4%

Diabetes mellitus[a]
- HbA_{1c} ≥6.5%

[a]Diagnosis to be confirmed if not unequivocal hyperglycemia (see Table 83–3).

PATHOGENESIS

Type 1 Diabetes Mellitus

Type 1 DM is characterized by an absolute deficiency of pancreatic β-cell function. Most often this is the result of an immune-mediated destruction of pancreatic β cells, but rare unknown or idiopathic processes may contribute. In immune mediated, a potential disruption of the T-helper 1/T-helper 2 balance may lead to higher T-helper 1 activity, with subsequent activation of the immune system and eventual destruction of pancreatic β cell. What is evident are four main features: (1) a long preclinical period marked by the presence of immune markers when β-cell destruction is thought to occur; (2) hyperglycemia when 80% to 90% of β cells are destroyed; (3) transient remission (the so-called "honeymoon" phase); and (4) established disease with associated risks for complications and death. Unknown is whether there is one or more inciting factors (e.g., cow's milk, or viral, dietary, or other environmental exposure) that initiate the autoimmune process[2] (Fig. 83–4). Vitamin D deficiency has been observed to be more prevalent in patients who develop type 1 DM, and potential mechanisms, including a role of vitamin D in reduction of interferon-γ and several interleukins, have been proposed. Observational data supports a potential role, but further study is needed.[17]

The autoimmune process is mediated by macrophages and T lymphocytes with circulating autoantibodies to various β-cell antigens. The most commonly detected antibody associated with type 1 DM is the islet cell antibody. The test for islet cell antibody, however, is difficult to standardize across laboratories. Other more readily measured circulating antibodies include insulin autoantibodies, antibodies directed against glutamic acid decarboxylase, insulin antibodies against islet tyrosine phosphatase, and several others. More than 90% of newly diagnosed persons with type 1 DM have one or another of these antibodies, as will 3.5% to 4% of unaffected first-degree relatives. Preclinical β-cell autoimmunity precedes the diagnosis of type 1 DM by up to 9 to 13 years. Autoimmunity may remit in some perhaps less-susceptible persons, or can progress to β-cell failure in others. These antibodies

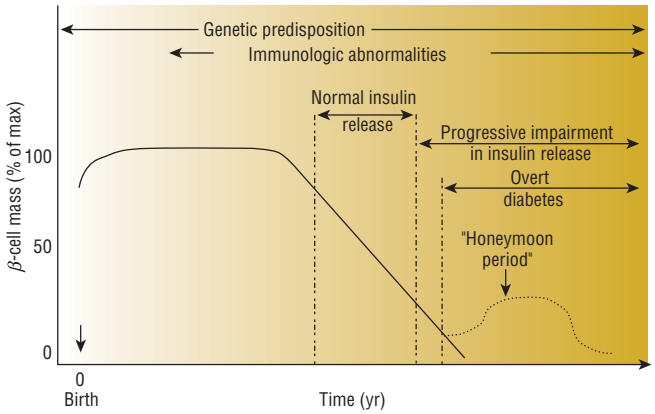

FIGURE 83-4. Scheme of the natural history of the β-cell defect in type 1 diabetes mellitus. *(Copyright © 2008 American Diabetes Association. From Medical Management of Type 1 Diabetes, Fifth Edition. Reprinted with permission from The American Diabetes Association.)*

are generally considered markers of disease rather than mediators of β-cell destruction. They have been used to identify individuals at risk for type 1 DM in evaluating disease prevention strategies. Other nonpancreatic autoimmune disorders are associated with type 1 DM, most commonly Hashimoto thyroiditis, but the extent of organ involvement can range from no other organs to polyglandular failure.[18]

There are strong genetic linkages to the *DQA* and *B* genes and certain human leukocyte antigens (HLAs) may be predisposing (*DR3* and *DR4*) or protective (*DRB1*04008-DQB1*0302* and *DRB1*0411-DQB1*0302*) on chromosome 6.[18] Other candidate gene regions have been identified on several other chromosomes as well. Because twin studies do not show 100% concordance, environmental factors such as infectious agents, chemical agents, and dietary agents are likely contributing factors in the expression of the disease.

Destruction of pancreatic β-cell function causes hyperglycemia due to an absolute deficiency of both insulin and amylin.[19] Insulin lowers blood glucose by a variety of mechanisms, including stimulation of tissue glucose uptake, suppression of glucose production by the liver, and suppression of free fatty acid (FFA) release from fat cells.[20] The suppression of free fatty acids plays an important role in glucose homeostasis. Increased levels of free fatty acids inhibit the uptake of glucose by muscle and stimulate hepatic gluconeogenesis.[21] Amylin, a glucoregulatory peptide hormone cosecreted with insulin, plays a role in lowering blood glucose by slowing gastric emptying, suppressing glucagon output from pancreatic alpha cells, and increasing satiety.[22] In type 1 DM, amylin production, due to β-cell destruction, is very low.

Type 2 Diabetes Mellitus

Normal Insulin Action In the fasting state 75% of total body glucose disposal takes place in non–insulin-dependent tissues: the brain and splanchnic tissues (liver and gastrointestinal tissues).[23] In fact, brain glucose uptake occurs at the same rate during fed and fasting periods and is not altered in type 2 diabetes.

The remaining 25% of glucose metabolism takes place in muscle, which is dependent on insulin.[24] In the fasting state approximately 85% of glucose production is derived from the liver, and the remaining amount is produced by the kidney.[24] Glucagon, produced by pancreatic α cells, is secreted in the fasting state to oppose the action of insulin and stimulate hepatic glucose production. Thus, glucagon prevents hypoglycemia or restores normoglycemia if hypoglycemia has occurred.[25] In the fed state, carbohydrate ingestion increases the plasma glucose concentration and stimulates insulin release from the pancreatic β cells. The resultant hyperinsulinemia (1) suppresses hepatic glucose production and (2) stimulates glucose uptake by peripheral tissues.[24] The majority (~80%–85%) of glucose that is taken up by peripheral tissues is disposed of in muscle, with only a small amount (~4%–5%) being metabolized by adipocytes. In the fed state, glucagon is suppressed.

Although fat tissue is responsible for only a small amount of total body glucose disposal, it plays a very important role in the maintenance of total body glucose homeostasis. Small increments in the plasma insulin concentration exert a potent antilipolytic effect, leading to a marked reduction in the plasma FFA level. The decline in plasma FFA concentration results in increased glucose uptake in muscle[24–28] and reduces hepatic glucose production.[29] Thus, a decrease in the plasma FFA concentration lowers plasma glucose by both decreasing its production and enhancing the uptake in muscle.

Type 2 diabetic individuals are characterized by (1) defects in insulin secretion; and (2) insulin resistance involving muscle, liver, and the adipocyte. Insulin resistance is present even in *lean* type 2 diabetic individuals (Fig. 83–5).

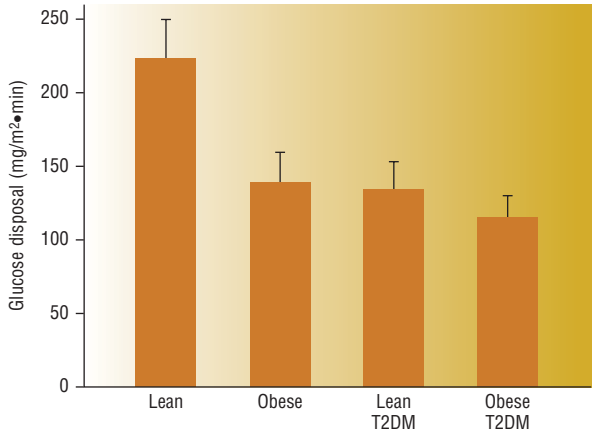

FIGURE 83-5. Whole body glucose disposal, a measure of insulin resistance, is reduced 40% to 50% in obese nondiabetic and lean type 2 diabetic individuals. Obese diabetic individuals are slightly more resistant than lean diabetic patients. *(From DeFronzo RA. Diabetes Reviews 1977;5:177–269.)*

Impaired Insulin Secretion The pancreas in people with a normal-functioning β cell is able to adjust its secretion of insulin to maintain normal glucose tolerance. Thus, in nondiabetic individuals, insulin is increased in proportion to the severity of the insulin resistance and glucose tolerance remains normal. Impaired insulin secretion is a uniform finding in type 2 diabetic patients and the evolution of β-cell dysfunction has been well characterized in diverse ethnic populations.

The fasting plasma insulin concentration and oral glucose tolerance tests in 77 normal-weight type 2 diabetic patients and over 100 lean subjects with normal or impaired glucose tolerance were examined (Fig. 83–6). The relationship between the fasting plasma glucose concentration and the fasting plasma insulin concentration resembles an inverted U or horseshoe. As the fasting plasma glucose concentration rises from 80 to 140 mg/dL, the fasting plasma insulin concentration increases progressively, peaking

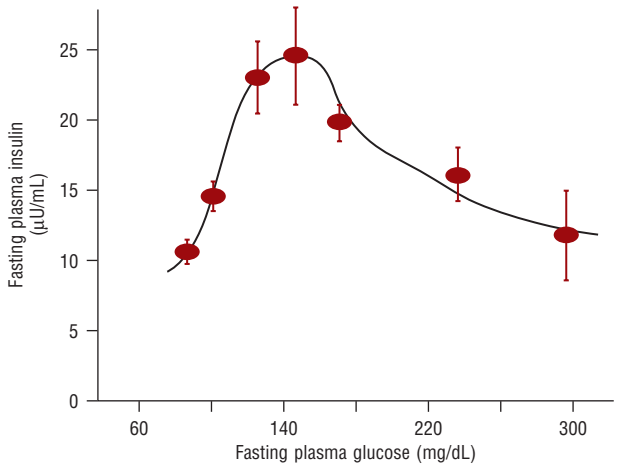

FIGURE 83-6. The relationship between fasting plasma insulin and fasting plasma glucose in 177 normal weight individuals. Plasma insulin and glucose increase together up to a fasting glucose of 140 mg/dL. When the fasting glucose exceeds 140 mg/dL, the β cell makes progressively less insulin, which leads to an overproduction of glucose by the liver and results in a progressive increase in fasting glucose. *(Reprinted from Med Clin N Am, Vol. 88., DeFronzo RA, Pathogenesis of type 2 diabetes mellitus, pages 787–835, Copyright © 2004, with permission from Elsevier.)*

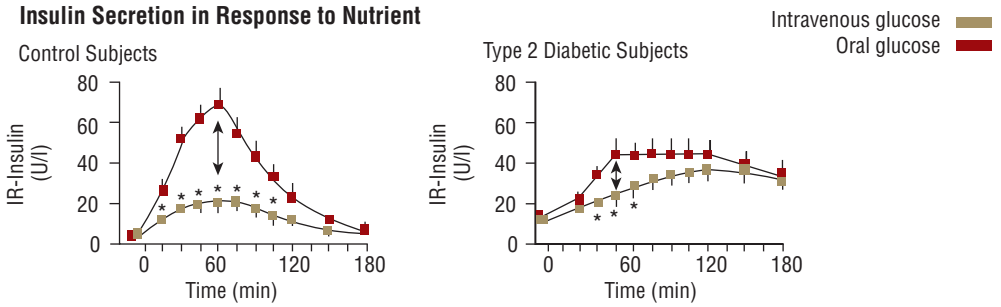

FIGURE 83-7. The loss of the incretin effect in type 2 diabetes mellitus. The plasma insulin responses to oral and intravenous glucose in nondiabetic subjects *(left)*, compared with patients with diabetes *(right)*. *(Adapted from Nauck M, Stockmann F, Ebert R, Creutzfeldt W. Reduced Incretin Effect in Type 2 (non-insulin dependent) diabetes. Diabetologia 1986;29:46–52.)*

at a value that is 2- to 2.5-fold greater than in normal weight nondiabetic controls. When the fasting plasma glucose concentration exceeds 140 mg/dL, the β cell is unable to maintain its elevated rate of insulin secretion and the fasting insulin concentration declines precipitously. This decrease in fasting insulin leads to an increase in hepatic glucose production overnight, which results in an elevated fasting plasma glucose concentration.[24]

In the type 2 diabetic patient, decreased postprandial insulin secretion is due to both impaired pancreatic beta cell function and a reduced stimulus for insulin secretion from gut hormones. The role gut hormones play in insulin secretion is best shown by comparing the insulin response to an oral glucose load versus an isoglycemic intraveneous glucose infusion. In nondiabetic control individuals 73% more insulin is released in response to an oral glucose load compared to reproducing the oral glucose load's plasma glucose curve by giving intravenous glucose (Fig. 83–7, left panel). This increased insulin secretion in response to an oral glucose stimulus is referred to as "the incretin effect" and suggests that gut-derived hormones when stimulated by glucose lead to an increase in pancreatic insulin secretion. In type 2 diabetic patients, this "incretin effect" is blunted with the increase in insulin secretion only being 50% of that seen in nondiabetic control individuals (Fig. 83–7). It is now known that two hormones, glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), are responsible for over 90% of the increased insulin secretion seen in response to an oral glucose load. Patients with type 2 diabetes remain sensitive to GLP-1 while they are often resistant to GIP.[25]

GLP-1 is secreted from the L-cells in the distal intestinal mucosa in response to mixed meals. Since GLP-1 levels rise within minutes of food ingestion neural signals initiated by food entry in the proximal gastrointestinal tract must simulate GLP-1 secretion. The insulinotropic action of GLP-1 is glucose dependent, and for GLP-1 to enhance insulin secretion, glucose concentrations must be higher than 90 mg/dL. In addition to stimulating insulin secretion, GLP-1 suppresses glucagon secretion, slows gastric emptying, and reduces food intake by increasing satiety. These effects of GLP-1 combine to limit postprandial glucose excursions. GIP is secreted by K-cells in the intestine and, like GLP, increases insulin secretion. However, GIP has no effect on glucagon secretion, gastric motility, or satiety. The half-life GLP-1 and GIP are short (<10 minutes). Both hormones are rapidly inactivated by removal of two N-terminal amino acids by the enzyme, dipeptidyl peptidase 4 (DPP-4). GLP-1 levels appears to decrease as glucose values increase from normal to type 2 DM.[25]

Site of Insulin Resistance in Type 2 Diabetes

Liver In type 2 diabetic subjects with mild to moderate fasting hyperglycemia (140–200 mg/dL, 7.8–1.1 mmol/L), basal hepatic glucose production is increased by ~0.5 mg/kg/min. Consequently, during the overnight sleeping hours the liver of an 80-kg diabetic individual with modest fasting hyperglycemia adds an additional 35 g of glucose to the systemic circulation. This increase in fasting hepatic glucose production is the cause of fasting hyperglycemia.[24]

Following glucose ingestion, insulin is secreted into the portal vein and carried to the liver, where it suppresses glucagon secretion and reduces hepatic glucose output. Type 2 diabetic patients fail to suppress glucagon in response to a meal and may even have a paradoxical rise in glucagon levels. Thus, hepatic insulin resistance and hyperglucagonemia result in continued production of glucose by the liver. Therefore, type 2 diabetic patients have two sources of glucose in the postprandial state, one from the diet and one from continued glucose production from the liver. These sources of glucose in combination with a shortened gastric emptying time may result in marked hyperglycemia.

Peripheral (Muscle) Muscle is the major site of glucose disposal in man, and approximately 80% of total body glucose uptake occurs in skeletal muscle. In response to a physiologic increase in plasma insulin concentration, muscle glucose uptake increases linearly, reaching a plateau value of 10 mg/kg/min. In contrast, in lean type 2 diabetic subjects, the onset of insulin action is delayed for ~40 minutes, and the ability of insulin to stimulate leg glucose uptake is reduced by 50%. Impaired insulin signaling is a well established abnormality, with notable impairments at almost every step of activation due to insulin resistance, lipo- and glucotoxicity. The compensatory hyperinsulinemia required to overcome impaired insulin signaling (insulin resistance) can activate an alternative pathway through MAP kinase, which may be involved in atherosclerosis. Mitochondrial dysfunction may also play a role in muscle insulin resistance. Mitochondrial function and density appear to be lower in some studies of type 2 DM. This may result in less energy expenditure and an increased risk of dysfunction with high-fat diets.[24]

Peripheral (Adipocyte) In obese nondiabetic and diabetic humans, basal plasma FFA levels are increased and fail to suppress normally after glucose ingestion. FFAs are stored as triglycerides in adipocytes and serve as an important energy source during conditions of fasting. Insulin is a potent inhibitor of lipolysis, and restrains the release of FFAs from the adipocyte by inhibiting the hormone-sensitive lipase enzyme. It is now recognized that chronically elevated plasma FFA concentrations can lead to insulin resistance in muscle and liver, and impair insulin secretion. In addition to FFAs that circulate in plasma in increased amounts, type 2 diabetic and obese nondiabetic individuals have increased stores of triglycerides in muscle and liver, and the increased fat content correlates closely with the presence of insulin resistance in these tissues.

In summary, insulin resistance involving both muscle and liver is a characteristic feature of glucose intolerance in type 2 diabetic individuals. In the basal state, the liver represents a major site of insulin resistance, and this is reflected by overproduction of glucose. This accelerated rate of hepatic glucose output is the primary determinant of the elevated fasting plasma glucose concentration in type 2 diabetic individuals. In the fed state, both decreased muscle glucose uptake and impaired suppression of hepatic glucose production contribute to the insulin resistance. In obese individuals and in the majority (>80%) of type 2 diabetic subjects, there is an expanded fat cell mass and the adipocytes are resistant to the antilipolytic effects of insulin. Most obese and diabetic individuals are characterized by expanded visceral adiposity, discussed in detail later in the chapter, which is especially refractory to insulin effects and results in a high lipolytic rate. Not surprisingly, both type 2 diabetes and obesity are characterized by an elevation in the mean 24-hour plasma FFA concentration. Elevated plasma FFA levels, as well as increased triglyceride/fatty acyl CoA content in muscle, liver, and β cells, lead to the development of muscle/hepatic insulin resistance and impaired insulin secretion.

Cellular Mechanisms of Insulin Resistance

Insulin resistance and the components of the insulin resistance syndrome are described below.

Obesity and Insulin Resistance Weight gain leads to insulin resistance, and obese nondiabetic individuals have the same degree of insulin resistance as lean type 2 diabetic patients. In 1,146 nondiabetic, normotensive individuals, a progressive loss of insulin sensitivity when the BMI increased from 18 kg/m^2 to 38 kg/m^2 was documented. The increase in insulin resistance with weight gain is directly related to the amount of visceral adipose tissue. Subsets of obese, but metabolically normal patients do exist, as well as nonobese, but metabolically abnormal patients, so broad categorization of risk for a patient needs to be confirmed by further examination.

The term *visceral adipose tissue* (VAT) refers to fat cells located within the abdominal cavity and includes omental, mesenteric, retroperitoneal, and perinephric adipose tissue. VAT has been shown to correlate with insulin resistance and explain much of the variation in insulin resistance seen in a population of African Americans. Visceral adipose tissue represents 20% of fat in men and 6% of fat in women. This fat tissue has been shown to have a higher rate of lipolysis than subcutaneous fat, resulting in an increase in FFA production. These fatty acids are released into the portal circulation and drain into the liver, where they stimulate the production of very-low-density lipoproteins and decrease insulin sensitivity in peripheral tissues. VAT also produces a number of cytokines, such as TNF-α, interleukin 6, and resistin, which contribute to insulin resistance. These factors drain into the portal circulation and reduce insulin sensitivity in peripheral tissues.

The fat cell also has the capability of producing at least one hormone that improves insulin sensitivity: adiponectin. This factor is made in decreasing amounts as an individual becomes more obese.[24] In animal models, adiponectin decreases hepatic glucose production and increases fatty acid oxidation in muscle.[24]

The Metabolic Syndrome The association of insulin resistance with a clustering of cardiovascular risk factors including hyperinsulinemia, hypertension, abdominal obesity, dyslipidemia, and coagulation abnormalities has been referred to by a variety of names including "insulin resistance syndrome," "metabolic syndrome," "dysmetabolic syndrome," and "the deadly quartet," to name a few. Since the description of the "insulin resistance syndrome" by Reaven in 1988,[26] the number of associated factors has continued to grow. Metabolic syndrome is a risk indicator, but not an absolute risk indicator, because it does not specifically account for all risk factors, such as age, sex, low-density lipoprotein cholesterol levels, or directly measure hypercoagulability of the proinflammatory condition. Patients with metabolic syndrome do have a higher risk for cardiovascular disease (CVD), and at least a 5-fold increase in their risk of type 2 DM.

The most recent definition of metabolic syndrome was adopted by multiple organizations in 2009 (Table 83–5).[27] Central obesity continues to be recognized as an important causative factor, but is no longer considered a prerequite to having metabolic syndrome. Central obesity can be easily assessed using waist circumference, which is a good surrogate marker for VAT. It is imperative to measure the waist circumference correctly (just above hip bones and just below umbilicus, tape measure should be taught, but not tight), for accurate assessment. Ethnic group specific cut-points for waist circumference are pragmatic estimates taken from various data sources. As more complete data becomes available these values may be modified. Table 83–5 lists the ethnic specific values for waist circumference.

Prevalence. Regardless of the definition used, large numbers of adults in the United States have metabolic syndrome. The National Health and Nutrition Examination Survey (NHANES) 1999–2002 is the most scientifically rigorous sample of the U.S. population.[28] A total of 3,601 men and women aged >20 years were included in the survey. Using the NCEP definition (Table 83–5), the prevalence of metabolic syndrome was 33.7% of men and 35.4% of women. In a sample of 4,060 predominantly European adults from South Australia, metabolic syndrome was present in 19.4% of men and 14.4% of women using the ATP III definition.[29]

The impact of treating the clinical components of the metabolic syndrome in diabetes patients was demonstrated in the Steno-2 Study.[30] In this prospective study, 63 patients with diabetes and microalbuminuria were randomized to the usual therapy group and 67 patients were treated intensively. Intensive therapy consisted of diet and exercise and pharmacologic intervention aimed at reducing hyperglycemia, hypertension, dyslipidemia, microalbuminuria, and increased coagulopathy (aspirin therapy). Treatment goals for intensive therapy included a blood pressure <130/80 mm Hg, HbA_{1c} <6.5%, total cholesterol <175 mg/dL, and triglycerides <150 mg/dL. All patients in the intensive treatment group were given an aspirin and treated with an angiotensin-converting enzyme (ACE) inhibitor. Patients in the intensively treated group showed a 53% relative risk reduction in cardiovascular disease and a 61% relative risk reduction in nephropathy. In this small study, the magnitude of this reduction is greater than has been demonstrated with individual interventions, stressing the importance of targeting all the components of the metabolic syndrome. The study design did not allow conclusions regarding which interventions had the most impact.

CLINICAL PRESENTATION

The clinical presentations of type 1 DM and type 2 DM are very different. Autoimmune type 1 DM can occur at any age. Approximately 75% will develop the disorder before age 20 years, but the remaining 25%, including relatives of index patients, develop the disease as adults. Individuals with type 1 DM are often thin and are prone to develop diabetic ketoacidosis if insulin is withheld, or under conditions of severe stress with an excess of insulin counterregulatory hormones.[3] Twenty percent to 40% of patients with type 1 DM present with diabetic ketoacidosis after several days of polyuria, polydipsia, polyphagia, and weight loss.

TABLE 83-5 Defining of the Metabolic Syndrome

Defining the Metabolic Syndrome NCEP ATP III: Five Components of the Metabolic Syndrome (Individuals Having at Least Three Components Meet the Criteria for Diagnosis)

Risk Factor	Defining Level
Abdominal obesity	Waist circumference
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
Triglycerides	≥150 mg/dL
High-density lipoprotein C	
Men	<40 mg/dL
Women	<50 mg/dL
Blood pressure	≥130/≥85 mm Hg
Fasting glucose	≥110 mg/dL

2009 Statement of the International Diabetes Federation Task Force on Epidemiology and Prevention; National Heart, Lung, and Blood Institute; American Heart Association; World Heart Federation; International Atherosclerosis Society; and International Association for the Study of Obesity

Criteria for Clinical Diagnosis of the Metabolic Syndrome

(Individuals having at least three components meet the criteria for diagnosis)

Measure	Categorical Cut Points
Elevated waist circumference[a]	Population- and country-specific definitions
Elevated triglycerides (drug treatment for elevated triglycerides is an alternate indicator)[b]	≥150 mg/dL (1.7 mmol/L)
Reduced HDL-C (drug treatment for reduced HDL-C is an alternate indicator)[b]	≤40 mg/dL (1.0 mmol/L) in males ≤50 mg/dL (1.3 mmol/L) in females
Elevated blood pressure Systolic ≥130 and/or diastolic ≥80 mm Hg (antihypertensive drug treatment in a patient with a history of hypertension is an alternate indicator)	
Elevated fasting glucose[c] (drug treatment of elevated glucose is an alternate indicator)	≥100 mg/dL

Current Recommended Waist Circumference Thresholds for Abdominal Obesity by Organization

Population	Organization (Reference)	Men (All values ≥)	Women (All values ≥)
Europid	IDF	94 cm	80 cm
Caucasian	WHO	94 cm(increased risk) 102 cm (still higher risk)	80 cm (increased risk) 88 cm (still higher risk)
Unites States	AHA/NHLBI (ATP III)	102 cm	88 cm
Canada	Health Canada	102 cm	88 cm
European	European European Cardiovascular Societies	102 cm	88 cm
Asia (including Japanese)	IDF	90 cm	80 cm
Asia	WHO	90 cm	80 cm
Japan	Japanese Obesity Society	85 cm	90 cm
China	Cooperative Task Force	85 cm	80 cm
Middle East	Mediterranean IDF	94 cm	80 cm
Sub-Saharan African	IDF	94 cm	80 cm
Ethnic Central and South American	IDF	90 cm	80 cm

HDL-C indicates high-density lipoprotein cholesterol.

[a]It is recommended that the IDF cut points be used for non-Europeans and either the IDF or AHA/NHLBI cut points used for people of European origin until more data are available.

[b]The most commonly used drugs for elevated triglycerides and reduced HDL-C are fibrates and nicotinic acid. A patient taking 1 of these drugs can be presumed to have high triglycerides and low HDL-C. High-dose –3 fatty acids presumes high triglycerides.

[c]Most patients with type 2 diabetes mellitus will have the metabolic syndrome by the proposed criteria.

Reproduced from Expert Panel on Detection.[124]

Occasionally, type 1 DM patients are diagnosed without multiple symptoms or diabetic ketoacidosis when they have blood tests drawn for other reasons. Because newly diagnosed patients with type 1 DM often have a small amount of residual pancreatic β-cell function, they may enter a "honeymoon" phase, when their blood glucose concentrations are relatively easy to control and small amounts of insulin are needed. Once this residual insulin secretion wanes, the patients are completely insulin deficient and tend to have more labile glycemia. Not all type 1 DM patients have complete insulin deficiency, and a small residual amount of insulin secretion is seen in some patients.

Patients with type 2 DM often present without symptoms, even though complications tell us that they may have been hyperglycemic for several years.[10] Often these patients are diagnosed secondary to unrelated blood testing. Lethargy, polyuria, nocturia, and polydipsia can be seen at diagnosis in type 2 diabetes, but significant weight loss at diagnosis is less common. Clinically, diabetes mellitus is a spectrum of diseases ranging from absolute insulin deficiency to relative insulin insulin deficiency, and patients can have normal to grossly abnormal insulin sensitivity. Classical clinical presentation characteristics should be used in conjuction with other definitive laboratory data to properly classify patients.

CLASSICAL CLINICAL PRESENTATION OF DIABETES MELLITUS[a]

Characteristic	Type 1 DM	Type 2 DM
Age	<30 years[b]	>30 years[b]
Onset	Abrupt	Gradual
Body habitus	Lean	Obese or history of obesity
Insulin resistance	Absent	Present
Autoantibodies	Often present	Rarely present
Symptoms	Symptomatic[c]	Often asymptomatic
Ketones at diagnosis	Present	Absent[d]
Need for insulin therapy	Immediate	Years after diagnosis
Acute complications	Diabetic ketoacidosis	Hyperosmolar hyperglycemic state
Microvascular complications at diagnosis	No	Common
Macrovascular complications at or before diagnosis	Rare	Common

[a]Clinical presentation can vary widely.
[b]Age of onset for type 1 DM is generally <20 years of age, but can present at any age. The prevalence of type 2 DM in children, adolescents, and young adults is increasing. This is especially true in ethnic and minority children.
[c]Type 1 may present acutely with symptoms of polyuria, nocturia, polydipsia, polyphagia, and weight loss.
[d]Type 2 children and adolescents are more likely to present with ketones, but after the acute phase may be treated with oral agents. Prolonged fasting can also produce ketones in individuals.

TREATMENT

Diabetes Mellitus

DESIRED OUTCOME

5 The primary goals of DM management are to reduce the risk for microvascular and macrovascular disease complications, to ameliorate symptoms, to reduce mortality, and to improve quality of life.[8] Near-normal glycemia will reduce the risk for development of microvascular disease complications, but aggressive management of traditional cardiovascular risk factors (i.e., smoking cessation, treatment of dyslipidemia, intensive blood pressure control, and antiplatelet therapy) are needed to reduce the likelihood of development of macrovascular disease. Evidence-based guidelines, as published by the ADA, may help in the attainment of these goals (Table 83–6).[8]

Hyperglycemia not only increases the risk for microvascular disease, but contributes to poor wound healing, compromises white blood cell function, and leads to classic symptoms of DM. Diabetic ketoacidosis and hyperosmolar hyperglycemic state are severe manifestations of poor diabetes control, almost always requiring hospitalization. Reducing the potential for microvascular complications is targeted at adherence to therapeutic lifestyle intervention (i.e., diet and exercise programs) and drug-therapy regimens, as well as at maintaining blood pressure as near normal as possible.

GENERAL APPROACH TO TREATMENT

Appropriate care requires goal setting for glycemia, blood pressure, and lipid levels, regular monitoring for complications, dietary and exercise modifications, medications, appropriate self-monitoring of blood glucose (SMBG), and laboratory assessment of the aforementioned parameters.[8] Glucose control alone does not sufficiently reduce the risk of macrovascular complications in persons with DM.

GLYCEMIC GOAL SETTING AND HEMOGLOBIN A1C

Controlled clinical trials provide ample evidence that glycemic control is paramount in reducing microvascular complications in both type 1 DM[31] and type 2 DM.[32] HbA_{1c} measurements are the gold standard for following long-term glycemic control for the previous 2 to 3 months.[33] Hemoglobinopathies, anemia, red cell membrane defects, transfusions, and any patient where the red blood cell lifespan is substantially increased or decreased can affect HbA_{1c} measurements. Minimization of problems, such as sickle cell trait, and assurance of standardized results can be accomplished by ensuring the test is performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the DCCT assay. Other strategies such as measurement of fructosamine, which measures glycated plasma proteins and correlates to glucose control over the last 2 to 3 weeks, may be necessary to assess diabetes control in patients with altered red blood cell lifespan, though the fructosamine is less standardized, and not correlated to risk of complications.

The A1C-Derived Average Glucose study correlated multiple HbA_{1c} and glucose readings to term a new phrase, estimated average glucose or eAG if abbreviated.[34] The eAG better correlates with HbA_{1c} readings, and now is regularly reported below HbA_{1c} values on laboratory results. For example, a HbA_{1c} of 6% or 7%, correlates with an average glucose of 126 mg/dL or 154mg/dL, respectively, and online calculators and graphs are easily found.

Less stringent HbA_{1c} goals (>7%) may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovascular complications or comorbidities, at risk elderly, dementia, or in younger children. A HbA_{1c} target of <7% is appropriate for others (Table 83–7), and lower values should be targeted if significant hypoglycemia, weight gain, and other adverse effects can be avoided.[8] New glycemic control recommendations for different age groups of type 1 DM patients are now recommended, based on the risk of hypoglycemia, the relatively low risk of complications prior to puberty, and psychological and/or developmental issues (Table 83–7).

MONITORING FOR COMPLICATIONS

The ADA recommends initiation of complications monitoring at the time of diagnosis of diabetes mellitus.[8] Current recommendations continue to advocate yearly dilated eye examinations in type 2 DM, and an initial dilated eye exam in the first 3 to 5 years in type 1 DM, then yearly thereafter. Less frequent testing (every 2–3 years) can be implemented upon the advice of an eye care specialist. The feet should be examined and the blood pressure assessed at each visit, with a distal polyneuropathy screen being performed yearly by simple tools, such as the 10-g force Semmes-Weinstein monofilament. A urine test for microalbumin once yearly from diagnosis is appropriate in type 2 DM, and initiated 5 years after diagnosis if the patient has type 1 DM. Yearly testing for lipid abnormalities, and more frequently if needed to achieve lipid goals, is recommended.

SELF-MONITORED BLOOD GLUCOSE AND CONTINUOUS GLUCOSE MONITORING

The advent of SMBG in the early 1980s revolutionized the treatment of DM, enabling patients to know their blood glucose

TABLE 83-6 Selected American Diabetes Association Evidence-Based Recommendations[a]

Recommendation Area	Specific Recommendation	Evidence Level[b]
Screening for diabetes	Screen overweight or obese at any age, those without risk factors should begin at 45 years.	B
	To screen for diabetes a FPG, 2-hour 75-g OGTT, or $HbAI_c$ are appropriate.	B
	Interval between screenings should be individualized based on risk, or every 3 years.	E
Monitoring	Home blood glucose monitoring is needed if on insulin.	A
	Subjects on other therapeutic interventions, including oral agents may need home blood glucose monitoring.	E
	Quarterly HbA_{Ic} in individuals not meeting glycemic goals, twice yearly in individuals meeting glycemic goals should be performed.	E
	In adults, measure fasting lipid profile at least annually.	E
	Perform an annual urine albumin excretion in type 1 diabetes with duration ≥5 years. Type 2 DM from diagnosis.	E
	All patients should be screened for polyneuropathy at diagnosis and at least annually thereafter.	B
	A dilated eye exam should be performed within 5 years of diagnosis in type 1 DM, and shortly after diagnosis in type 2 DM, with follow-up every year, or every 2–3 years as recommended by an eye specialist.	B
Glycemic goals	HbA_{Ic} goal for patients in general is <7%.	B
	HbA_{Ic} goal should be individualized, with <7% if achieved without significant hypoglycemia or adverse effects.	B
	Less stringent HbA_{Ic} goal may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovascular complications or comorbidities, or in younger children.	C
Treatment		
Prevention of type 2 diabetes	Patients with IGT (A), IFG (E), or an A1C of 5.7–6.4% (E) should attempt weight loss (5%–10%), increasing physical activity.	See text
	Metformin may be considered in obese, <60-year-old patients at very high risk of diabetes, including "near" diabetes glucose or A1C, HTN, first-degree family history of diabetes.	E
Medical nutrition therapy	Weight loss is recommended for all insulin-resistant/overweight or obese individuals. Either low-carbohydrate or low-fat calorie restricted diets may work.	A
	In types 1 and 2 DM, intensive vs standard glucose control have not shown a significant reduction in CVD during randomized portions, but long-term follow-up of DCCT and UKPDS have shown targeting below A_{1C} <7% may reduce long-term macrovascular disease.	B
	Saturated fat should be <7% of total calories.	A
	Monitoring carbohydrate intake by carbohydrate counting or exchanges is recommended.	A
	Glycemic index may give modest benefits over total carbohydrate intake.	B
Physical activity	150 minutes/week of moderate intensity exercise is recommended or 90 minutes of vigourous exercise/week.	A
	Resistance training of large muscle groups should be 3 × week.	A
Blood pressure	Systolic blood pressure should be treated to <130 mm Hg.	C
	Diastolic blood pressure should be treated to <80 mm Hg.	B
	Initial drug therapy should be with an ACE inhibitor or ARB.	C
Nephropathy	Type 1 DM with any degree of albuminuria-ACE inhibitor.	A
	Type 2 DM with microalbuminuria-ACE inhibitor or ARB.	A
	Type 2 DM with macroalbuminuria-angiotensin receptor blocker.	A
Dyslipidemia	The primary goal is an LDL <100 mg/dL.	A
	Statin therapy should be added to lifestyle, regardless of baseline lipid levels if patient has CVD, >40 years of age, and one other CVD risk fact.	A
	In patients with overt CVD, using a statin to acheive a LDL <70 mg/dL is an optional goal.	B
	Triglycerides should be lowered to <150 mg/dL.	C
	Raising HDL to >40 mg/dL in men and >50 mg/dL in women.	C
Antiplatelet	Use aspirin (75–162 mg daily) for secondary cardioprotection.	A
	Use aspirin (75–162 mg) for primary prevention in type 1 or 2 DM if the 10-year risk of CVD is >10%, or at least one additional risk factor is present.	C
	Clopidogrel (75 mg/day) is appropriate for patients with CVD and documented aspirin allergy.	B

[a]Based on American Diabetes Association Practice Recommendations[8]

[b]Evidence levels:

A = Clear evidence from well-conducted, generalizable, randomized controlled trials that are adequately powered.

B = Supportive evidence from well-conducted cohort studies or well-conducted case-control study.

C = Supportive evidence from poorly controlled or uncontrolled studies or conflicting evidence with weight of evidence supporting intervention.

E = Expert consensus or clinical experience.

concentration at any moment easily and relatively inexpensively. Frequent SMBG is necessary to achieve near-normal blood glucose concentrations and to assess for hypoglycemia and hyperglycemia, adjust prandial doses of insulin, and give corrective doses of insulin. This is particularly true in patients with type 1 DM, as most will be intensively managed with insulin.[33] The more intense the pharmacological regimen is, the more intense the SMBG needs to be (four or more times daily in patients on multiple insulin injections or pump therapy whether type 1 or type 2 DM). The optimal frequency of SMBG for patients with type 2 DM on oral agents is unresolved. Frequency of monitoring in type 2 DM should be sufficient to facilitate reaching glucose goals and to test for hypoglycemia. The role of SMBG in improving glycemic control in type 2 DM patients is controversial, but has shown to reduce the HbA_{Ic} ~0.4% to no improvement.[35] What is clear is that patients must be empowered to change their therapeutic regimen (lifestyle and medications) in response to test results, or no meaningful glycemic improvement is likely to be effected.

Alternate site testing may improve adherence to SMBG recommendations, but only SMBG meters that can "sip" blood onto the strip will accommodate such testing. Alternate site glucose testing may be performed on alternative parts of the body, such as

TABLE 83-7 Glycemic Goals of Therapy by Organization and for Type 1 DM[8]

Biochemical index	ADA		ACE and AACE
Hemoglobin A_{1c}	<7%[a]		≤6.5%
Preprandial plasma glucose	70–130 mg/dL (3.9–7.2 mmol/L)		<110 mg/dL
Postprandial plasma glucose	<180 mg/dL[b] (<10 mmol/L)		<140 mg/dL
ADA plasma glucose and HbA_{1c} goals for type 1 DM by age group[c]			
Values by age (years)	Plasma glucose goal		A_{1C}
	Before meals bedtime/overnight		
Toddlers and preschoolers (0–6)	100–180	110–200	<8.5% (but >7.5%)
School age (6–12)	90–180	100–180	<8.0%
Adolescents and young adults (13–19)	90–130	90–150	<7.5%

ADA, American Diabetes Association; ACE, American College of Endocrinology; AACE, American Association of Clinical Endocrinologists; DCCT, Diabetes Control and Complications Trial.

[a]Assay should be National Glycohemoglobin Standardization Program (NGSP) certified measurement and DCCT standardized. More stringent glycemic control may be appropriate if accomplished without significant hypoglycemia or adverse effects. Less stringent HbA_{1c} goals may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovascular complications or comorbidities, at-risk elderly, dementia, or in younger children.

[b]Postprandial glucose measurements should be made 1–2 hours after the beginning of the meal, generally the time of peak levels in patients with diabetes.

[c]Vulnerability to hypoglycemia and relatively low risk of complication prior to puberty considered. Adolescents and youg adults may have adult goals if without developmental and psychological issues, and if without excessive hypoglycemia.

the palm, forearm, thigh, and stomach. These areas tend to have less nerve endings and may be more comfortable for a patient, but several cautions must be observed. Alternate site glucose readings will lag behind fingertip capillary blood, as the capillary flow and density is often less in the alternate testing sites when compared with the fingertip. Alternate site testing is discouraged in any situation where immediate action will be needed based on the glucose reading, such as testing for hypoglycemia or in patients with hypoglycemia unawareness, wide fluctuations in SMBG, or when the blood glucose is know to be fluctuating, such as postprandially.

CLINICAL CONTROVERSY

SMBG improves glycemic control when insulin is used, but few well-conducted studies have shown significant glycemic reductions with increasing use of home blood glucose testing for type 2 DM patients not on insulin. The average HbA_{1c} reduction with use of SMBG in type 2 DM patients not on insulin was 0.4%, though others have reported no glycemic improvement.[33] Patients must be empowered to change their therapeutic regimen (lifestyle and medications) in response to test results, or no meaningful glycemic improvement is likely to be effected, and thus the money spent on the strip is wasted.

Continuous glucose monitoring (CGM) may be useful in select patients. CGM measures interstitial glucose, which lags behind capillary SMBG, and the same cautions as alternate site testing should be followed. CGM can be useful in patients with frequent hypoglycemia or hypoglycemic unawareness, nocturnal hypoglycemia, for identification of fluctuating glucose patterns and/or previously unknown problems in patients with higher than expected HbA_{1c} results. CGM still needs to be calibrated multiple times a day with SMBG readings to ensure accuracy, and a new sensor must be placed every 3 to 7 days. The ADA currently recommends that CGM can be considered in type 1 DM adults ≥25 years of age, and in others with the above issues noted.

NONPHARMACOLOGIC THERAPY

Diet

Medical nutrition therapy is recommended for all persons with DM and along with activity, is a cornerstone of treatment.[36] Paramount for all medical nutrition therapy is the attainment of optimal metabolic outcomes and the prevention and treatment of complications. For individuals with type 1 DM, the focus is on regulating insulin administration with a balanced diet to achieve and maintain a healthy body weight. A meal plan that is moderate in carbohydrates and low in saturated fat (<7% of total calories), with a focus on balanced meals is recommended. The amount (grams) and type (via the glycemic index, though controversial) of carbohydrates, whether accounted for by exchanges or carbohydrate counting, should be considered.[36] It is imperative that patients understand the connection between carbohydrate intake and glucose control. In addition, patients with type 2 DM often require caloric restriction to promote weight loss, and portion size and frequency are often issues. Rather than a set diabetic diet, advocate a diet using foods that are within the financial reach and cultural milieu of the patient. As most patients with type 2 DM are overweight or obese, bedtime and between-meal snacks are not needed if pharmacologic management is appropriate.

Activity

In general, most patients with DM can benefit from increased activity.[37] Aerobic exercise improves insulin sensitivity and glycemic control in the majority of individuals, and reduces cardiovascular risk factors, contributes to weight loss or maintenance, and improves well-being. The patient should choose an activity that she or he is likely to continue. Start exercise slowly in previously sedentary patients. It remains unclear which asymptomatic patients should be screened for CVD prior to the beginning of an exercise regimean. It may be reasonable in patients with long-standing disease (age >35 years, or >25 years old with DM ≥10 years), patients with multiple cardiovascular risk factors, presence of microvascular disease (especially renal disease), and patients with previous evidence of atherosclerotic disease should have a cardiovascular evaluation, probably including an

electrocardiogram, with further workup related to CVD risk. In addition, several complications (uncontrolled hypertension, autonomic neuropathy, insensate feet, and retinopathy) may require restrictions on the activities recommended. Physical activity goals include at least 150 minutes/week of moderate (50%–70% maximal heart rate) intensity exercise. In addition, resistance training, in patients without retinal contraindications, is recommended for 30 minutes 3 times/week.

PHARMACOLOGIC THERAPY

Until 1995, only two options for pharmacologic treatment were available for patients with diabetes; sulfonylureas (for type 2 DM only) and insulin (for type 1 or 2). Since 1995, a number of new oral agents, injectables, and insulins have been introduced in the United States.

Currently, eight classes of oral agents are approved for the treatment of type 2 diabetes: α-glucosidase inhibitors, biguanides, meglitinides, peroxisome proliferator activated receptor γ agonists (which are also commonly identified as thiazolidinediones or glitazones), dipeptidyl peptidase 4 (DPP-4) inhibitors, dopamine agonists, bile acid sequestrants, and sulfonylureas. Oral antidiabetic agents are often grouped according to their glucose-lowering mechanism of action. Biguanides and thiazolidinediones are often categorized as insulin sensitizers due to their ability to reduce insulin resistance. Sulfonylureas and meglitinides are often categorized as insulin secretagogues because they enhance endogenous insulin release.

Diabetes treatment options continue to evolve, with newer oral agents and non-insulin injectables potentially altering future algorithms for the treatment of diabetes. The subsequent sections describe the current antidiabetic medications that are available to treat type 1 and type 2 diabetes mellitus.

Drug Class Information

Insulin ***Pharmacology.*** Insulin is an anabolic and anticatabolic hormone. It plays major roles in protein, carbohydrate, and fat metabolism. For a complete review of insulin action, the reader is referred to a diabetes physiology text.[38] Endogenously produced insulin is cleaved from the larger proinsulin peptide in the β cell to the active peptide of insulin and C-peptide, which can be used as a marker for endogenous insulin production. All commercially available insulin preparations contain only the active insulin peptide.

Characteristics. Characteristics that are commonly used to categorize insulins include source, strength, onset, and duration of action. Additionally, insulins may be characterized as analogs, defined as insulins that have had amino acids within the insulin molecule modified and/or "modifiers" added to impart particular physiochemical and pharmacokinetic advantages. Table 83–8 summarizes available insulin preparations.

U-100 and U-500, 100 units/mL and 500 units/mL, respectively, are the strengths of injectable insulin currently available in the United States. U-500 regular insulin is available for individuals that may require large doses of insulin to control their diabetes. In the United States, all other insulins are available only in U-100 strength. For some type 1 diabetes patients who require extremely low doses of insulin, dilution of U-100 insulin to obtain accurate insulin doses may be necessary. Diluents and empty bottles can be obtained from the manufacturers for dilution.

Historically, insulin came from either beef or pork sources. Beef insulin differs by three amino acids and pork by one amino acid when compared to human insulin. Manufacturers in the United States have discontinued production of beef and pork source insulins as of December 2003, and now exclusively use recombinant DNA technology to manufacture insulin. Eli Lilly and Sanofi-Aventis currently use a non–disease-producing strain of *Escherichia coli* for synthesis of insulin; whereas Novo Nordisk uses *Saccharomyces cerevisiae*, or bakers' yeast, for synthesis.

Purity of insulin refers to the amount of proinsulin and other impurities present in a given insulin product. Prior to 1980, most insulin contained enough impurities (300–10,000 ppm) to cause local reactions upon injection, as well as systemic adverse effects from antibody production. Modern technology has provided less expensive techniques to purify insulin. As a result, all insulin products contain ≤10 ppm of proinsulin, with purified preparations (all recombinant DNA human insulin and insulin analogs) containing <1 ppm of proinsulin.

Regular crystalline insulin naturally self-associates into a hexameric (six insulin molecules) structure when injected subcutaneously. Before absorption through a blood capillary can occur, the hexamer must dissociate first to dimers, and then to monomers. This principle is the premise for additives such as protamine and zinc described below, and modification of amino acids for insulin analogs. Lispro, aspart, and glulisine insulins dissociate rapidly to monomers, thus absorption is rapid. Lispro (B-28 lysine and B-29 proline human insulin; monomeric) insulin with two amino acids transposed, aspart (B-28 aspartic acid human insulin; mono- and dimeric) insulin with replacement of one amino acid, and glulisine (B-3 lysine and B-29 glutamic acid) are rapidly absorbed, peak faster, and have shorter durations of action when compared to regular insulin. Proteins tend to be insoluable near their isoelectric point, and glargine insulin uses this to prolong absorption. In comparison to human insulin, with an isoelectric point of 5.4, the analog glargine insulin (A-21 glycine, B-30a-arginine, B-30a L-arginine, and B-30b L-arginine human insulin) has an isoelectric point of 6.8. In the bottle, glargine is buffered to a pH of 4, a level at which it is completely soluble, resulting in a clear colorless solution. When injected into the neutral pH of the body, it rapidly forms microprecipitates that slowly dissolve into monomers and dimers which are then subsequently absorbed. The result is a long-acting, 24-hour duration insulin analog. Detemir, in contrast, attaches a C14 fatty acid (a 14 carbon fatty acid) at the B-29 position and removes the B-30 amino acid. This allows the fatty acid side chain to bind to interstitial albumin at the SQ injection site. Also, the formulation allows stronger hexamer (six molecules of insulin associated together) self associations, which prolong absorption. Once detemir dissociates from the interstitial albumin, it is free to enter a capillary, where it is again bound to albumin, which can further prolong action. It then travels to a site of action and interacts, after dissociation from albumin, with insulin receptors.

Insulin analogs are modified human insulin molecules, and safety is paramount for FDA approval. Key factors that should be considered in the approval process include local injection reactions, antigenicity, efficacy compared to human insulin, insulin receptor binding affinity, and insulin-like growth factor 1–receptor affinity (which is compared to that of human insulin to determine mitogenic potential).

Pharmacokinetics. Subcutaneous injection kinetics are dependent on onset, peak, and duration of action, and are summarized in Table 83–9. Absorption of insulin from a subcutaneous depot is dependent on several factors, including source of insulin, concentration of insulin, additives to the insulin preparations (e.g., zinc, protamine, etc), blood flow to the area (rubbing of injection area, increased skin temperature, and exercise in muscles near the injection site may enhance absorption), and injection site. Regular or NPH insulin is commonly injected in (from most

TABLE 83-8 Available Injectable and Insulin Preparations

Generic Name	Manufacturer	Analog[a]	Administration Options	Room Temperature[b] Expiration
Rapid-acting insulins				
Humalog (insulin lispro)	Lilly	Yes	Insulin pen 3-mL, vial, or 3-mL pen cartridge	28 days
NovoLog (insulin aspart)	Novo Nordisk	Yes	Insulin pen 3-mL, vial, or 3-mL pen cartridge	28 days
Apidra (insulin glulisine)	Sanofi-Aventis	Yes	Insulin pen 3-mL, vial, or 3-mL pen cartridge	28 days
Short-acting insulins				
Humulin R (regular) available in U-100 and U-500	Lilly	No	U-100, 10-mL vial U-500, 20-mL vial	28 days
Novolin R (regular)	Novo Nordisk	No	10-mL vial	30 days
Intermediate-acting insulins				
NPH				
Humulin N	Lilly	No	Vial, 3-mL prefilled pen	Vial: 28 days; pen: 14 days
Novolin N	Novo Nordisk	No	Vial	30 days
Long-acting insulins				
Lantus (insulin glargine)	Sanofi-Aventis	Yes	Vial, 3-mL pen, 3-mL pen cartridge	28 days
Levemir (insulin detemir)	Novo nordisk	Yes	Vial, 3-mL prefilled pen	42 days
Premixed insulins				
Premixed insulin analogs				
Humalog Mix 75/25 (75% neutral protamine lispro, 25% lispro)	Lilly	Yes	Vial, prefilled pen	Vial: 28 days; pen: 10 days
Novolog Mix 70/30 (70% aspart protamine suspension, 30% aspart)	Novo Nordisk	Yes	Vial, 3-mL prefilled pen	Vial: 28 days; others: 14 days
Humalog Mix 50/50 (50% neutral protamine lispro/ 50% lispro)	Lilly	Yes	Vial, 3-mL pen	Vial: 28 days; pen:10 days
NPH-regular combinations				
Humulin 70/30	Lilly	No	Vial, 3-mL prefilled pen	Vial: 28 days; pen: 10 days
Novolin 70/30	Novo Nordisk	No	Vial	30 days
Other injectables				
Glucagon like peptide-1 agonists	**(GLP-1 Agonists)**			
Byetta (exenatide)	Amylin/Lilly	No	5 mcg and 10 mcg pen, ~60 injections (doses)/pen	30 days (≤77°F)
Victoza (liraglutide)	Novo Nordisk	Yes	3-mL pen, can deliver 0.6 mg, 1.2 mg, or 1.8 mg dose	30 days
Amylinomimetic				
Symlin (pramlintide)	Amylin	Yes	5-mL vial, 1.5 mL pen: delivers 15, 30, 45, or 60 mcg dose; 2.7 mL pen: delivers 60 or 120 mcg dose	30 days

[a]All diabetes injectables available in the U.S. are now made by human recombinant DNA technology. An insulin analog is a modified human insulin molecule that imparts particular pharmacokinetic advantages.
[b]Room temperature defined as 59°–86°F. All products are good until expiration date on product if unopened and stored correctly.

rapid to slowest absorption): abdominal fat, posterior upper arms, lateral thigh area, and superior buttocks area. Insulin analogs, unlike regular or NPH insulin, appear to retain their kinetic profile at all sites of injection. U-500 regular insulin has a delayed onset, peak, and a longer duration of action when compared to U-100 insulin. Addition of protamine (NPH, NPL, and aspart protamine suspension) or excess zinc (historically lente or ultralente insulin) will delay onset, peak, and duration of the insulin's effect. Variability in absorption, inconsistent suspension of the insulin by the patient or healthcare provider when drawing up a

TABLE 83-9 Pharmacokinetics of Various Insulins Administered Subcutaneously

Type of Insulin	Onset (Hours)	Peak (Hours)	Duration (Hours)	Maximum Duration (Hours)	Appearance
Rapid acting					
Aspart	15–30 min	1–2	3–5	5–6	Clear
Lispro	15–30 min	1–2	3–4	4–6	Clear
Glulisine	15–30 min	1–2	3–4	5–6	Clear
Short-acting					
Regular	0.5–1.0	2–3	4–6	6–8	Clear
Intermediate acting[a]					
NPH	2–4	4–8	8–12	14–18	Cloudy
Long acting					
Detemir	2 hours	—[b]	14–24[c]	24	Clear
Glargine	4–5	—[b]	22–24[c]	24	Clear

[a]Lente and Ultralente insulin has been discontinued.
[b]Glargine is considered "flat" pharmacokinetically, and detemir has a slight peak, but both have exhibited peak effects during comparative testing, and these peak effects may necessitate changing therapy in a minority of type 1 DM patients.
[c]See text for further discussion.

dose, and inherent insulin action based on the pharmacokinetics of the products may all contribute to a labile glucose response. NPH and all suspension based insulins should be inverted or rolled gently at least 10 times to fully resuspend the insulin prior to each use.

As detemir insulin has a unique mechanism to prolong absorption, it should not be surprising that the pharmacokinetics are unique. Detemir insulin reported less intrapatient variability between injections (less "wobble" in insulin levels between injections) when compared with NPH or glargine insulin. This may be advantageous when variability in the insulin level may make a large difference in glycemic excursions, as in type 1 DM. It should be noted, at low dose (0.2 units/kg) the duration of action is approximately 14 to 16 hours, while at doses above 0.3units/kg, it is close to 24 hours. In type 1 DM, 30%–50% of patients may require twice daily use of detemir insulin to cover 24 hour basal insulin needs, but this is unlikely to be an issue in type 2 DM patients, as they tend to use more units per day to attain glycemic goals. Direct comparative data between glargine insulin and detemir insulin is difficult to interpret, as detemir insulin was allowed to be dosed twice daily. Equivalent glycemic control was attained with either insulin. It is possible that glargine insulin in a minority of type 1 DM patients may pharmacokinetically require twice daily dosing, but this is poorly documented in the literature.

The half-life of an intravenous (IV) injection of regular insulin is about 9 minutes. Thus the effective duration of action of a single IV injection is short, and changes in IV insulin rates will reach steady state in approximately 45 minutes. Intravenous pharmacokinetics of other soluble insulins (lispro, aspart, glulisine, and even glargine) are similar to IV regular insulin, but they have no advantages over IV regular insulin and are more expensive. For completeness, aspart and glulisine are both FDA approved for intravenous use.

Insulin is degraded in the liver, muscle, and kidney. Liver deactivation is 20% to 50% in a single passage. Approximately 15% to 20% of insulin metabolism occurs in the kidney. This may partially explain the lower insulin dosage requirements in patients with end-stage renal disease.

Currently, insulin must be injected to retain its glycemic lowering properties. Alternative absorption pathways, including pulmonary, topical, gastrointestinal, an even nasal are being explored. The first inhalation insulin was discontinued due to poor sales and subsequent reports of lung cancer, but Technosphere inhaled insulin (Afrezza) has been submitted to the FDA for review. The onset of action is similar to IV insulin, which is unique.

An educated patient in conjunction with a skilled practitioner can usually achieve excellent glycemic control with insulin therapy. Efficacy with insulin therapy is related to achieving glycemic control while minimizing the risk of potential side effects, specifically hypoglycemia and weight gain. Insulin is recommended in patients with extremely high fasting plasma glucose levels (>280–300 mg/dL) or HbA_{1c}, patients with ketonuria or ketonemia, symptomatic patients (weight loss with polyuria, polydipsia, and/or nocturia), gestational diabetes mellitus, pregnancy with diabetes, and if deemed appropriate by the clinician and patient.[39–42]

Microvascular Complications. Insulin has been shown to be as efficacious as any oral agent for treating DM. The United Kingdom Prospective Diabetes Study, which used sulfonylureas or insulin, showed equal efficacy in lowering the risk of microvascular events in newly diagnosed type 2 DM.[32] Similarly, in type 1 DM, the Diabetes Control and Complications Trial showed efficacy in reducing microvascular complications.[31]

Macrovascular Complications. The connection between high insulin levels (hyperinsulinemia), insulin resistance, and cardiovascular events incorrectly leads some clinicians to believe that insulin therapy may cause macrovascular complications. The UKPDS and DCCT found no differences in macrovascular outcomes with intensive insulin therapy. One study, the Diabetes Mellitus, Insulin Glucose Infusion in Acute Myocardial Infarction study[43] reported reductions in mortality with insulin therapy. This group assessed the effect of an insulin-glucose infusion in type 2 DM patients who had experienced an acute myocardial infarction. Those randomized to insulin infusion followed by intensive insulin therapy lowered their absolute mortality risk by 11% over a mean follow-up period of approximately 3 years. This was most evident in subjects who were insulin-naïve or had a low cardiovascular risk prior to the acute myocardial infarction.[43] The importance of glycemic control in hospitalized patients is covered later in the chapter.

Adverse Effects. The most common adverse effects reported with insulin are hypoglycemia and weight gain. Hypoglycemia is more common in patients on intensive insulin therapy regimens versus those on less-intensive regimens. Also, patients with type 1 DM tend to have more hypoglycemic events compared to type 2 DM patients. In the UKPDS study, performed over 10 years, the percentage of diabetic patients that needed assistance (third-party or hospitalization) due to a hypoglycemic reaction was 2.3%. The UKPDS reported a rate of 36.5% for risk of any hypoglycemic event, including mild, self-treated events. In the DCCT, tighter control produced a risk three times higher for severe hypoglycemia compared to conventional therapy. Glycemic goals should incorporate hypoglycemic risk versus the benefit of lowering the glucose when HbA_{1c} levels are near normal, especially in type 1 DM.

Minimization of risk for patients on insulin should include education about the signs and symptoms of hypoglycemia, proper treatment of hypoglycemia, and blood glucose monitoring. Blood glucose monitoring is essential for those on insulin, and is particularly of value in patients with hypoglycemia unawareness. Patients with hypoglycemia unawareness do not experience the normal sympathetic symptoms of hypoglycemia (tachycardia, tremulousness, and often, sweating). Initial hypoglycemia symptoms are neuroglycopenic in nature (confusion, agitation, loss of consciousness, and/or progression to coma). Patients with hypoglycemia unawareness should at least temporarily raise their glycemic goals (requiring a reduction in insulin dose) and check their blood glucose level prior to any activities that may be dangerous with a low blood sugar (e.g., driving and certain sports, among others). Proper treatment of hypoglycemia dictates ingestion of carbohydrates, with glucose being preferred. Unconsciousness is an indication for either IV glucose, or glucagon injection, which increases glycogenolysis in the liver. Glucagon use would be appropriate in any situation in which the patient does not have or cannot have ready IV access for glucose administration. Education for reconstitution and injection of glucagon is recommended for close friends and family of a patient who has recurrent neuroglycopenic events. The patient and close contacts should be informed that it can take 10 to 15 minutes for the injection to start raising glucose levels, and patients often vomit during this time. Proper positioning to avoid aspiration should be emphasized.

Weight gain is predominantly from increased truncal fat, and tends to be related to daily dose and plasma insulin levels present. Weight gain is undesirable in most type 2 DM patients, but may be seen as beneficial in underweight patients with type 1 DM. Weight gain appears to be related to intensive insulin therapy, and can be somewhat minimized by physiologic replacement of insulin.

Two forms of lipodystrophy, though much less common today in people with diabetes, still occur. Lipohypertrophy is caused by many injections into the same injection site. Due to insulin's anabolic actions, a raised fat mass is present at the injection site with

resultant variable insulin absorption. Lipoatrophy, in contrast, is thought to be due to insulin antibodies or allergic type-reactions with destruction of fat at the site of injection. Injection away from the site with more purified insulin is recommended, though reports of lipoatrophy have been reported with most insulin preparations. Anecdotal evidence has shown that specially formulated cromolyn may help to stabilize the allergic type of reaction.

One large database associated glargine insulin with a higher risk of breast cancer, and possibly colon and pancreatic cancer, but other large database studies have shown no such association. Glargine in vitro has a higher affinity for IGF-1 than regular human insulin, which could theoretically explain the increased risk of cancer. However, in the observational, retrospective study, patients on glargine were older than patients on the comparator NPH insulin, which may explain the increased cancer rate observed. Supporting this premise, when glargine was used in intensive insulin therapy regimens in healthier populations, no such association was seen.

Drug–Drug Interactions. There are no significant drug–drug interactions with injected insulin, though other medications that may affect glucose control can be considered. Detemir does not have albumin binding interactions, as it occupies only a small percent of albumin binding sites. Table 83–10 lists common medications known to affect blood glucose levels.

Dosing and Administration. The dose of insulin for any person with altered glucose metabolism must be individualized. In type 1 DM, the average daily requirement for insulin is 0.5 to 0.6 units/kg, with approximately 50% being delivered as basal insulin, and the remaining 50% dedicated to meal coverage. During the honeymoon phase it may fall to 0.1 to 0.4 units/kg. During acute illness or with ketosis or states of relative insulin resistance, higher dosages are warranted. In type 2 DM a higher dosage is required for those patients with significant insulin resistance. Dosages vary widely depending on underlying insulin resistance and concomitant oral insulin sensitizer use. Strategies on how to initiate and monitor insulin therapy will be described later in the therapeutics section.

TABLE 83-10 Medications That May Affect Glycemic Control[a]

Drug	Effect on Glucose	Mechanism/Comment
Angiotensin-converting enzyme inhibitors	Slight reduction	Improves insulin sensitivity
Alcohol	Reduction	Reduces hepatic glucose production
α-Interferon	Increase	Unclear
Atypical antipsychotics	Increase	Decrease insulin sensitivity; weight gain
Calcineurin inhibitors	Increase	Decrease insulin secretion
Diazoxide	Increase	Decreases insulin secretion, decreases peripheral glucose use
Diuretics (thiazides)	Increase	May increase insulin resistance
Glucocorticoids	Increase	Impairs insulin action
Fluoroquinolones	Increase/ Decrease	Unclear, potential drug interaction with sulfonylureas or change in insulin secretion
Nicotinic acid	Increase	Impairs insulin action, increases insulin resistance
Oral contraceptives	Increase	Unclear
Pentamidine	Decrease, then increase	Toxic to β cells; initial release of stored insulin, then depletion
Phenytoin	Increase	Decreases insulin secretion
Protease inhibitors	Increase	Worsen insulin resistance
β-Blockers	May increase	Decreases insulin secretion
Ranolazine	Decrease	Improves oxidative glucose disposal
Salicylates	Decrease	Inhibition of I-κ-B kinase-β(IKK-beta) (only high doses, e.g., 4–6 g/day)
Sympathomimetics	Slight increase	Increased glycogenolysis and gluconeogenesis

[a]This list is not inclusive of all medications reported to cause glucose changes.

Storage. It is recommended that unopened injectable insulin be refrigerated (36°–46°F) prior to use. The manufacturer's expiration date printed on the insulin is used for unopened, refrigerated insulin. Once the insulin is in use, the manufacturer-recommended expiration dates will vary based on the insulin and delivery device. Table 83–8 outlines manufacturer-recommended expiration dates for room temperature (59°–86°F) insulin. For financial reasons, patients may attempt to use insulins longer than their expiration dates, but careful attention must be paid to monitoring for glycemic control deterioration and signs of insulin decay (clumping, precipitates, discoloration, etc.) if this is attempted.

Glucagon-Like Peptide 1 Agonists

Exenatide ***Pharmacology.*** Exendin 4 is a 39-amino acid peptide isolated from the saliva of the Gila monster (Heloderma suspectum) and shares approximately 50% amino acid sequence with human glucagon-like peptide 1 (GLP-1). Exenatide is the synthetic version of naturally occuring exendin 4. Exenatide (Byetta) has been shown to bind to GLP-1 receptors in many parts of the body including the brain and pancreas. Exenatide and GLP-1 have common glucoregulatory actions. Exenatide enhances glucose dependent insulin secretion while suppressing inappropriately high postprandial glucagon secretion in the presence of elevated glucose concentrations, resulting in a reduction in hepatic glucose production. Exenatide increases satiety, which may result in weight loss, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose disposition. The GLP-1 receptor activity is pharmacologic, and is approximately 3 to 4 times the normal peak physiologic GLP-1 activity. This is necessary to obtain gastric emptying and satiety effects, which are not seen at physiologic GLP-1 levels.

Pharmacokinetics. Exenatide concentrations are detectable in plasma within 10 to 15 minutes after subcutaneous injection, and the drug has a t_{max} of ~2 hours and a plasma half life of ~3.3 to 4.0 hours. Exenatide plasma concentrations increase in a dose-dependent manner and plasma exenatide concentrations are detectable for up to 10 hours postinjection, though pharmacodynamically, effects last for approximately 6 hours. Bioavailability of exenatide after injection in the abdomen, upper arm, or the thigh is similar. Elimination of exenatide is primarily by glomerular filtration with subsequent proteolytic degradation. When exenatide is administered to subjects with worsening degrees of renal insufficiency, there is a progressive prolongation of the half-life, and in dialysis patients, plasma clearance of exenatide is markedly reduced. The incidence of gastrointestinal side effects appears to be increased in individuals with impaired renal function, possibly due to higher plasma levels, thus caution is advised.

No significant differences in exenatide pharmacokinetics have been observed with obesity, race, gender, or advancing age (up to 73 years old).

Efficacy. The average HbA_{1c} reduction is approximately 0.9% with exenatide, though, similar to oral agents, it is dependent upon the baseline HbA_{1c} values. Three phase III trials reported similar HbA_{1c} reduction in patients on metformin, sulfonylureas, or both. It is recommended to lower the sulfonylurea dose only if GLP-1 agonists are started with near normal glucose levels. Sulfonylureas release insulin in a non-glucose dependent fashion and can cause occasional severe hypoglycemia. Exenatide significantly decreases postprandial glucose excursions, but has only a modest effect on

fasting plasma glucose values. If a patient has significant elevations in fasting plasma glucose levels, these should be corrected with other agents, and the exenatide added on. Exenatide may aid some patients' efforts to lose weight. The average weight loss in controlled trials was 1 to 2 kg over 30 weeks, without dietary advice being given to the patients, though long-term, open-label follow-up on 10 mcg BID shows continued and sustained weight loss for at least 3 years.[44] Approximately 84% of patients on exenatide lost some weight. Exenatide, through decreasing appetite and slowing gastric emptying, may reduce the number of calories a patient eats at a meal. If a patient does not decrease calorie intake, as exenatide does not increase caloric expenditure, no weight loss is likely to occur.

Microvascular Complications. Exenatide reduces the HbA_{1c} level, which has been shown to be related to the risk of microvascular complications.

Macrovascular Complications. No randomized clinical trials have examined the effect of exenatide on cardiovascular outcomes. Meta-analysis data reported a 30% (P = NS) reduction in the risk of cardiovascular events. Improvements in several cardiovascular risk factors have been reported. Plasma triglycerides (−37 ± 10 mg/dL) decreased, and plasma HDL cholesterol (+4.5 ± 0.4 mg/dL) increased on open-label exenatide 10 mcg BID. Nonsignificant reductions in systolic and diastolic blood pressure were observed in the whole population, though a significant reduction was seen in subjects with above normal systolic blood pressure. The greatest improvement in cardiovascular risk factors was, in general, seen in subjects who had the greatest weight loss.[44]

Adverse Effects. The most common adverse effects associated with exenatide are gastrointestinal in nature. Nausea occurs in ~40% of subjects on 5 mcg, and ~45% to 50% of subjects on 10 mcg BID. Vomiting or diarrhea occurs in approximately 10% of patients placed on exenatide. Gastrointestinal adverse effects appear to decrease over time, but approximately 1 in 20 patients may have prolonged problems with one of the above side effects, possibly requiring discontinuation. As these adverse effects appear to be dose releated, the patient should be started on a 5 mcg BID and titrated to 10 mcg BID only if the adverse effects are mostly gone. Also, when the patient is increased to the 10 mcg BID dose, these adverse effects may recur for a short period of time. Many episodes of nausea would be better characterized as stomach fullness, and patients should be instructed to eat slowly and stop eating when full, or risk nausea/vomiting. Also, weight loss appears not to be related to adverse effects, but rather to a reduction in calories consumed. Exenatide provides glucose-dependent insulin secretion, thus hypoglycemic rates when combined with metformin or a thiazolidinedione are not substantially increased, but when combined with a sulfonylurea or insulin, significant hypoglycemia may occur. Though exenatide reduces glucagon when the glucose is high, no suppression of counter-regulatory hormones has been noted during hypoglycemia. Exenatide antibodies can occur, but generally decrease over time and do not affect glycemic control. In approximately 5% of patients, titers may increase over time, resulting in a blunting of glycemic control in about half of these patients. Exenatide has been associated with the serious adverse effect of acute pancreatitis, but this has not been shown to be causal. Further study is needed, but several important points should be noted: (1) type 2 DM patients have many risk factors for pancreatitis such as gallstones, hypertriglyceridemia, obesity, and concommitant medication use; (2) GLP-1 agonists can mask initial signs of pancreatitis, as nausea, vomiting, and abdominal pain are common signs of pancreatitis; and (3) large database studies have not linked exenatide to a higher rate of acute pancreatitis. Clinically, do not use exenatide in a patient with a history of pancreatitis, and if a patient with abdominal pain, nausea, and/or vomiting presents it is best to discontinue exenatide temporarily and clinically confirm that it is not a sign of a more serious underlying problem. Exenatide given twice daily does not change the risk of thyroid C-cell tumors in rats, and no signal for C-cell tumors has been reported in humans.

Drug Interactions. Exenatide delays gastric emptying, thus it can delay the absorption of other medications. Examples of medications that may be effected include oral pain medications and antibiotics dependent on concentration dependent killing. If rapid absorption of the medication is necessary, it is best to take the mediation one hour before, or at least 3 hours after the injection of exenatide. In addition, if the patient has gastroparesis, exenatide is not recommended.

Dosing and Administration. Exenatide dosing should be started with 5 mcg BID, and titrated to 10 mcg BID in 1 month or when tolerability allows and if warranted for glycemic control. Exenatide should be injected 0 to 60 minutes before the morning and evening meals. If the patient does not eat breakfast, they may take the first injection of the day at lunch. The peak effect of exenatide is at approximately 2 hours, so anecdotally the patient may get better appetite suppression if injected an hour prior to the meal. Storage and dosage availability information can be found in Table 83–8.

Liraglutide ***Pharmacology.*** Liraglutide (Victoza) is a GLP-1 receptor agonist. Liraglutide enhances glucose-dependent insulin secretion while suppressing inappropriately high glucagon secretion in the presence of elevated glucose concentrations, resulting in a reduction in hepatic glucose production. Liraglutide reduces food intake, which may result in weight loss, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose disposition. During hypoglycemia, liraglutide does not stimulate insulin secretion and does not inhibit the release of the counterregulatory hormone glucagon. Liraglitide is produced through recombinant DNA technology, similar to the way insulin is made by the manufacturer, Novo Nordisk. Liraglitide has 97% amino acid sequence homology to endogenous GLP-1, with the only alteration being an arginine for lysine at position 34. A C-16 fatty acid (palmitic acid) is attached at position 26 (with a glutamic amino acid spacer to optimize GLP-1 receptor interaction) so that liraglutide can bind noncovalently to albumin, prolonging the half-life.

Pharmacokinetics. Self-association into a heptameric structure, and binding to albumin first in the interstitial space, then the blood, then the interstitial space around the GLP-1 receptor prolongs the half-life. In healthy individuals, the half-life is 13 hours, making it suitable for daily administration. Injection into the abdomen, upper arm, and thigh gave clinically similar pharmacokinetics, and the absolute bioavailability is approximately 50%. Maximum concentrations are reached approximately 8 to 12 hours after injection, and steady state is reached after approximately 3 days. Liraglutide has a mean apparent volume of distribution of 13 liters, and is extensively plasma protein bound (mostly to albumin as previously stated). The elimination half-life is 10 to 18 hours. Metabolism appears to be by degredation, similar to other large proteins, and several small minor metabolites (total of 3%–5% of the dose) may be found. The DPP-4 enzyme in vitro has been shown to slowly metabolize liraglutide, and this may be the case in vivo as well. The pharmacokinetics do not appear to be affected by age, race, and gender. Severe renal or mild to severe hepatic impairment may actually lower the AUC by approximately 25%, though the clinical significance of this on multiple dosing is not known.

Efficacy. The average HbA_{1c} reduction is approximately 1.1% with liraglutide, though, similar to oral agents, it is dependent on the baseline HbA_{1c} values. Phase III trials have been completed for monotherapy, metformin, sulfonylureas, both, or metformin plus

rosiglitazone. HbA_{1c} reduction with monotherapy 1.2 mg or 1.8 mg daily dose was significantly better than glimepiride 8 mg daily over 52 weeks. Liraglutide 1.2 mg (−0.9%) and 1.8 mg (−1.1%) daily sustained HbA_{1c} reductions over 2 years, but glimepiride 8 mg daily (−0.6%) did not sustain the HbA_{1c} reduction. Liraglutide consistently lowered the fasting plasma glucose level by approximately 25 to 40 mg/dL, and postprandial plasma glucose levels are reduced similarly. Due to the longer half-life, liraglutide can suppress glucagon overnight, which improves the fasting plasma glucose. Similar to exenatide, liraglutide treated patients may lose weight. The average weight loss in controlled trials was 1 to 3 kg over 26 weeks, and weight loss achieved appeared to be sustained through 2 years. Liraglutide, through decreasing appetite and slowing gastric emptying, may reduce the number of calories a patient eats at a meal.

Microvascular Complications. Liraglutide reduces the HbA_{1c} level, which has been shown to be related to the risk of microvascular complications.

Macrovascular Complications. No published clinical trials have examined the effect of liraglutide on cardiovascular outcomes, though no signal of cardiovascular harm was noted upon FDA approval.

Adverse Effects. The most common adverse effects associated with liraglutide are gastrointestinal in nature. Nausea occurs in ~11% to 29% of subjects on 1.2 mg, and 14% to 40% of subjects on 1.8 mg daily. Vomiting may occur in approximately 5% of subjects, and diarrhea occurs in approximately 8% to 15% of patients placed on liraglutide. Gastrointestinal adverse effects appear to decrease over time, but approximately 5% to 10% of subjects withdrew due to gastrointestinal side effects. As these adverse effects appear to be dose releated, the patient should be titrated from 0.6 mg, to 1.2 mg, and to 1.8 mg as tolerated. Randomized trials did not allow for individualized titration, and likely had worse tolerability that can be obtained clinically by individualization of titration. Many episodes of nausea would be better characterized as stomach fullness, and patients should be instructed to eat slowly and stop eating when full, or risk nausea/vomiting. Liraglutide provides glucose-dependent insulin secretion, and hypoglycemic rates when combined with metformin ± a thiazolidinedione are not substantially increased, but when combined with a sulfonylurea or insulin, significant hypoglycemia may occur. When combined with a sulfonylurea, the rates of hypoglycemia were similar between addition of liraglutide or glargine insulin. Liraglutide antibodies can occur (4%–13%), but the rates are generally low and do not affect glycemic control or risk of side effects.

Liraglutide has been associated with the serious adverse event of acute pancreatitis, but this risk has not been shown to be causal. Further study is needed, but type 2 DM patients have many risk factors for pancreatitis such as gallstones, hypertriglyceridemia, obesity, and concommitant medication use. GLP-1 agonists can mask initial signs of pancreatitis, as nausea, vomiting, and abdominal pain are common signs of pancreatitis. Clinically, do not use liraglutide in a patient with a history of pancreatitis. If a patient with abdominal pain, nausea, and/or vomiting presents, it is best to discontinue liraglutide temporarily and proceed with an initial workup for pancreatitis.

A black box warning about thyroid C-cell tumors is listed on the package insert of liraglutide. Rodent models reported a higher risk of C-cell tumors of the thyroid, including medullary thyroid carcinoma. Medullary thyroid carcinoma, if not caught early, has high mortality rates, but rodents may simply be a poor model to study this effect as they express many more GLP-1 receptors on their thyroid than human beings. In addition, calcitonin, a marker used to screen for C-cell tumors, may increase by a non-clinically significant amount in select patients. No signal for C-cell tumors in humans or non-human primates has been noted, and as clinical use increases, this will be reexamined. No monitoring is currently recommended, but liraglutide is contraindicated in patients with a personal or family history of medullary thyroid cancer, or if they have a history of multiple endocrine tumors.

Drug Interactions. Liraglutide delays gastric emptying, thus it can delay the absorption of other medications. Examples of medications that may be effected include oral pain medications and antibiotics dependent on threshold levels for efficacy. If rapid absorption of the medication is necessary, it is best to take the mediation 1 hour before, or at least 3 hours after the injection. Liraglutide may worsen gastroparesis and clinically it may not be prudent to use in this patient population.

Dosing and Administration. Dosing of liraglutide should be at 0.6 mg daily for ≥1 week, and then increased to 1.2 mg daily for ≥1 week. Patients may be maintained on the 1.2-mg dose, or increased to the maximum dose of 1.8 mg daily after ≥1 week. The 0.6-mg dose is considered a titration dose, and does not reduce the HbA_{1c} substantially in the majority of patients. This titration is recommended to improve gastrointestinal tolerability, and titration should be individualized based on side effects and clinical response. Dosing is daily, and can be given independent of meals. As with exenatide, the reduction in insulin secretagogues may be necessary if the patient is near glycemic goal. Storage and dosage availability information can be found in Table 83–8.

Exenatide versus Liraglutide. In a head-to-head trial in type 2 DM subjects given metformin, sulfonylurea, or both over 26 weeks, liraglutide 1.8 mg daily lowered HbA_{1c} (−1.1%) significantly more than exenatide 10 mcg BID (−0.8%). Liraglutide was better at reduction of fasting plasma glucose, but exenatide was slightly better at reduction of postprandial glucose. Both resulted in approximately 3-kg weight loss, and minor hypoglycemic events were slightly less frequent with liraglutide (26%) than with exenatide BID (34%). Nausea rates were similar for liraglutide (26%) and exenatide (28%), but the rate of persistence was lower with liraglutide, being below 10% by week 6, whereas exenatide did not reach this level until after week 22. No significant changes in calcitonin were noted and there were no reports of pancreatitis, but a small, significant increase in heart rate was noted with liraglutide (+3.3 beats per minute) versus exenatide (+0.7 beats per minute).[45]

Amylinomimetic

Pramlintide ***Pharmacology.*** Pramlintide (Symlin) is an antihyperglycemic agent used in patients currently treated with insulin. Pramlintide is a synthetic analog of amylin (amylinomimetic), a neurohormone co-secreted from the β cells with insulin. Amylin is very low or absent in type 1 DM, and lower than normal in type 2 DM patients requiring insulin therapy. Pramlintide is provided as a 37-amino acid polypeptide, which differs in amino acid sequence from human amylin by replacement positions 25 (alanine), 28 (serine), and 29 (serine) with proline. Pramlintide suppresses inappropriately high postprandial glucagon secretion, increases satiety, which may result in weight loss, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose disposition.

Pharmacokinetics. The absolute bioavailability of pramlintide after subcutaneous injection is 30% to 40%. The t_{max} is approximately 20 minutes, but the C_{max} is dose dependent and appears to be linear. The $t_{1/2}$ is approximately 45 minutes, thus the pharmacodynamic duration of action is about 3 to 4 hours. Pramlintide does not extensively bind to albumin, and should not have significant binding interactions. Metabolism is primarily by the kidneys, and one active metabolite (2–37 pramlintide) has a similar half-life as

the parent compound. No accumulation has been seen in renal insufficiency, but caution is advised. Injection into the arm may increase exposure and variability of absorption, so injection into the abdomen or thigh is recommended. Moderate to severe renal insufficiency does not affect exposure.

Efficacy. The average HbA_{1c} reduction is approximately 0.6% with pramlintide, though optimization of the insulin and pramlintide doses may result in further drops in HbA_{1c}. If the 120-mcg dose is used in type 2 DM patients on insulin, it may also result in 1.5-kg weight loss. In type 1 DM patients, the average reduction in HbA_{1c} was 0.4% to 0.5%. Prandial pramlintide added versus rapid-acting insulin in type 2 DM subjects uncontrolled on basal insulin reported similar efficacy, but with no weight gain, compared with ~5-kg weight gain with rapid-acting insulin. Pramlintide decreases prandial glucose excursions, but has little effect on the fasting plasma glucose concentration. When pramlintide is injected before the meal, gastric emptying may delay absorption of mealtime nutrients, necessitating delay of rapid-acting insulin. This may be overcome by injecting the meal-time insulin at the conclusion of the meal, or whenever the blood glucose starts to rise. The average weight loss in controlled trials was 1 to 2 kg, without dietary advice being given to the patients. Pramlintide, through decreasing appetite and slowing gastric emptying, may reduce the number of calories a patient eats at a meal.

Microvascular Complications. Pramlintide reduces the HbA_{1c} level, which has been shown to be related to the risk of microvascular complications.

Macrovascular Complications. No published clinical trials have examined the effect of pramlintide on cardiovascular outcomes.

Adverse Effects. The most common adverse effects associated with pramlintide are gastrointestinal in nature. Nausea occurs in ~20% of type 2 DM patients, and vomiting or anorexia occurs in approximately 10% of type 1 or type 2 DM patients. Nausea is more common in type 1 DM, occuring in ~40% to 50% of patients. The higher rate in type 1 DM related to gastrointestinal adverse effects appear to decrease over time and are dose releated, thus starting at a low dose and slowly titrating as tolerated is recommended. Pramlintide alone does not cause hypoglycemia, but it is indicated for use in patients on insulin, thus hypoglycemia can occur. The risk of severe hypoglycemia early in therapy is higher in type 1 DM than in type 2 DM patients. A 2-fold increase in severe hypoglycemic reactions in type 1 DM patients has been reported.

Drug Interactions. Pramlintide delays gastric emptying, thus it can delay the absorption of other medications. Examples of medications that may be effected include oral pain medications and antibiotics dependent on threshold levels for efficacy. If rapid absorption of the medication is necessary, it is best to take the mediation 1 hour before, or at least 3 hours after the injection of pramlintide.

Dosing and Administration. Pramlintide dosing varies in type 1 and type 2 DM. It is imperative that the prandial insulin dose, if used, be reduced 30% to 50% when pramlintide is started to minimize severe hypoglycemic reactions. Basal insulin may need to be adjusted only if the fasting plasma glucose is close to normal. In type 2 DM, the starting dose is 60 mcg prior to meals, and may be titrated to the maximally recommended 120-mcg dose as tolerated and warranted based on postprandial plasma glucose concentrations. In type 1 DM dosing starts at 15 mcg prior to meals, and can be titrated up in 15-mcg increments to a maximum of 60 mcg prior to each meal if tolerated and warranted. Snacks may or may not need to be covered with pramlintide (recommended if ≥250 kcal or ≥30 g of carbohydrate is eaten). Pramlintide in a vial allows individualization of titration at even smaller increments (by units) than the package insert recommends, which may be useful in some type 1 DM patients. Each 2.5 units on a U-100 insulin syringe = 15 mcg of pramlintide. In addition, pramlintide has a pH of 4, and it is not recommended that pramlintide be mixed with any other insulin, thus this potentially adds additional injections a day. The addition of a pen device does help with the extra injections, but does not allow for smaller than recommended titrations. Storage information can be found in Table 83–8.

Sulfonylureas ***Pharmacology.*** The primary mechanism of action of sulfonylureas is enhancement of insulin secretion. Sulfonylureas bind to a specific sulfonylurea receptor (SUR) on pancreatic β cells. Binding closes an adenosine triphosphate–dependent K^+ channel, leading to decreased potassium efflux and subsequent depolarization of the membrane. Voltage-dependent Ca^{+2} channels open and allow an inward flux of Ca^{+2}. Increases in intracellular Ca^{+2} bind to calmodulin on insulin secretory granules, causing translocation of secretory granules of insulin to the cell surface and resultant exocytosis of the granule of insulin. Elevated secretion of insulin from the pancreas travels via the portal vein and subsequently suppresses hepatic glucose production.

Classification. Sulfonylureas are classified as first-generation and second-generation agents. The classification scheme is largely derived from differences in relative potency, relative potential for selective side effects, and differences in binding to serum proteins (i.e., risk for protein-binding displacement drug interactions). First-generation agents consist of acetohexamide, chlorpropamide, tolazamide, and tolbutamide. Each of these agents is lower in potency relative to the second-generation drugs: glimepiride, glipizide, and glyburide (Table 83–11). It is important to recognize that all sulfonylureas are equally effective at lowering blood glucose when administered in equipotent doses.

Pharmacokinetics. All sulfonylureas are metabolized in the liver; some to active, others to inactive metabolites (see Table 83–11). Cytochrome P450 (CYP450) 2C9 is involved with the hepatic metabolism of the majority of sulfonylureas. Agents with active metabolites or parent drug that are renally excreted require dosage adjustment or use with caution in patients with compromised renal function. The half-life of the sulfonylurea also relates directly to the risk for hypoglycemia. The hypoglycemic potential is therefore higher with chlorpropamide and glyburide. The long duration of effect of chlorpropamide may be particularly problematic in elderly individuals, whose renal function declines with age, and therefore it has great potential for accumulation, resulting in severe and protracted hypoglycemia. Individuals at high risk for hypoglycemia (e.g., elderly individuals and those with renal insufficiency or advanced liver disease) should be started at a very low dose of a sulfonylurea with a short half-life. Hypoglycemia on low-dose sulfonylureas may dictate a therapy without the risk of hypoglycemia, or a short-acting insulin secretagogue (nateglinide or repaglinide).

Efficacy. As mentioned earlier, when given in equipotent doses, all sulfonylureas are equally effective at lowering blood glucose. On average, HbA_{1c} will fall 1.5% to 2%, with fasting plasma glucose reductions of 60 to 70 mg/dL, but is dependent on baseline values. A majority of patients will not reach glycemic goals with sulfonylurea monotherapy. Patients who fail sulfonylurea usually fall into two groups: Those with low C-peptide levels and high (>250 mg/dL) fasting plasma glucose (FPG) levels. These patients are often primary failures on sulfonylureas (<30 mg/dL drop of FPG) and have significant glucose toxicity or slow-developing type 1 DM. The other group is those with a good initial response (>30 mg/dL drop of FPG), but which is insufficient to reach their glycemic goals. Over 75% of patients fall into the second group. Factors that portend a positive response include newly diagnosed patients with no indicators of type

TABLE 83-11 Oral Agents for the Treatment of Type 2 Diabetes Mellitus

Generic Name (Generic Version Available? Y = yes, N = no)	Brand	Dose (mg)	Recommended Starting Dosage (mg/day)		Equivalent Therapeutic Dose (mg)	Maximum Dose (mg/day)	Duration of Action	Metabolism or Therapeutic Notes

Sulfonylureas								
Acetohexamide (Y)	Dymelor	250, 500	250	125–250	500	1500	Up to 16 hours	Metabolized in liver; metabolite potency equal to parent compound; renally eliminated
Chlorpropamide (Y)	Diabinese	100, 250	250	100	250	500	Up to 72 hours	Metabolized in liver; also excreted unchanged renally
Tolazamide (Y)	Tolinase	100, 250, 500	100–250	100	250	1,000	Up to 24 hours	Metabolized in liver; metabolite less active than parent compound; renally eliminated
Tolbutamide (Y)	Orinase	250, 500	1,000–2,000	500–1,000	1,000	3,000	Up to 12 hours	Metabolized in liver to inactive metabolites that are renally excreted
Glipizide (Y)	Glucotrol	5, 10	5	2.5–5	5	40	Up to 20 hours	Metabolized in liver to inactive metabolites
Glipizide (Y)	Glucotrol XL	2.5, 5, 10, 20	5	2.5–5	5	20	24 hours	Slow-release form; do not cut tablet
Glyburide (Y)	DiaBeta Micronase	1.25, 2.5, 5	5	1.25–2.5	5	20	Up to 24 hours	Metabolized in liver; elimination 1/2 renal, 1/2 feces
Glyburide, micronized (Y)	Glynase	1.5, 3, 6	3	1.5–3	3	12	Up to 24 hours	Equal control, but better absorption from micronized preparation
Glimepiride (Y)	Amaryl	1, 2, 4	1–2	0.5–1	2	8	24 hours	Metabolized in liver to inactive metabolites
Short-acting insulin secretagogues								
Nateglinide (Y)	Starlix	60, 120	120 with meals	120 with meals	NA	120 mg 3 times a day	Up to 4 hours	Metabolized by cytochrome P450 (CYP450) 2C9 and 3A4 to weakly active metabolites; renally eliminated
Repaglinide (N)	Prandin	0.5, 1, 2	0.5–1 with meals	0.5–1 with meals	NA	16	Up to 4 hours	Caution with gemfibrozil or trimethoprim-potential hypoglycemia
Biguanides								
Metformin (Y)	Glucophage	500, 850, 1,000	500 mg twice a day	Assess renal function	NA	2550	Up to 24 hours	No metabolism; Renally secreted and excreted
Metformin ER (Y)	Glucophage XR	500, 750, 1,000 mg	500–1,000 mg with evening meal	Assess renal function	NA	2,550	Up to 24 hours	Take full dose with evening meal or may split dose; may consider trial if intolerant to immediate release
Thiazolidinediones								
Pioglitazone (N)	Actos	15, 30, 45	15	15	NA	45	24 hours	Metabolized by CYP 2C8 and 3A4; two metabolites have longer half-lives than parent compound

TABLE 83-11 Oral Agents for the Treatment of Type 2 Diabetes Mellitus (continued)

Generic Name (Generic Version Available? Y = yes, N = no)	Brand	Dose (mg)	Recommended Starting Dosage (mg/day)		Equivalent Therapeutic Dose (mg)	Maximum Dose (mg/day)	Duration of Action	Metabolism or Therapeutic Notes
			Nonelderly	*Elderly*				
Rosiglitazone (N)	Avandia	2, 4, 8	2–4	2	NA	8 mg/day or 4 mg twice a day	24 hours	Metabolized by CYP2C8 and 2C9 to inactive metabolites that are renally excreted
α-Glucosidase inhibitors								
Acarbose (Y)	Precose	25, 50, 100	25 mg 1–3 times a day	25 mg 1–3 times a day	NA	25–100 mg 3 times a day	1–3 hours	Eliminated in bile
Miglitol (N)	Glyset	25, 50, 100	25 mg 1–3 times a day	25 mg 1–3 times a day	NA	25–100 mg 3 times a day	1–3 hours	Eliminated renally
Dipeptidyl peptidase 4 inhibitors (DPP-4 inhibitors)								
Sitagliptin (N)	Januvia	25, 50, 100	100 mg daily	25–100 mg daily based on renal function	NA	100 mg daily	24 hours	50 mg daily if creatinine clearance >30 to <50 mL/min; 25 mg if creatinine clearance <30 mL/min
Saxagliptin (N)	Onglyza	2.5, 5	5 mg daily	2.5–5 mg daily based on renal function	NA	5 mg daily	24 hours	2.5 mg daily if creatinine clearance <50 mL/min or if on strong inhibitors of CYP3A4/5
Bile Acid Sequestrants								
Colesevelam (N)	Welchol	625 mg tablet 1.875 g and 3.75 g oral suspension	6 tablets daily or 3 tablets BID 1.875 g BID or 3.75 g daily	6 tablets daily or 3 tablets BID 1.875 g BID or 3.75 g daily	NA	3.75 g/day	Not absorbed, local effect ~6 hours	Constipation may occur. Cautions: drug–drug absorption interactions, may increase triglycerides; contraindicated if TG >500 mg/dL
Dopamine agonist								
Bromocriptine mesylate (N)	Cycloset	0.8 mg tablets	1.6–4.8 mg daily	1.6–4.8 mg daily	NA	4.8 mg daily	4–5 hours	Take within 2 hours of rising with food. Significant nausea, other side effects, and drug–drug, drug–disease interactions may occur. See text for detailed information
Combination products								
Glyburide/metformin (Y)	Glucovance	1.25/250 2.5/500 5/500	2.5–5/500 twice a day	1.25/250 twice a day; assess renal function	NA	20 of glyburide, 2,000 of metformin	Combination medication	Use as initial therapy: 1.25/250 mg twice a day
Glipizide/metformin (Y)	Metaglip	2.5/250 2.5/500 5/500	2.5–5/500 twice a day	2.5/250; assess renal function	NA	20 of glipizide, 2,000 of metformin	Combination medication	Use as initial therapy: 2.5/250 mg twice a day
Rosiglitazone/metformin (N)	Avandamet	1/500 2/500 4/500 2/1,000 4/1,000	1–2/500 twice a day	1/500 twice a day assess renal function	NA	8 of rosiglitazone; 2,000 of metformin	Combination medication	Past manufacturing problems, but recently reintroduced to market. May use as initial therapy

TABLE 83-11 Oral Agents for the Treatment of Type 2 Diabetes Mellitus (continued)

Generic Name (Generic Version Available? Y = yes, N = no)	Brand	Dose (mg)	Recommended Starting Dosage (mg/day)		Equivalent Therapeutic Dose (mg)	Maximum Dose (mg/day)	Duration of Action	Metabolism or Therapeutic Notes
			Nonelderly	*Elderly*				
Rosiglitazone/ glimepiride (N)	Avandaryl	4/1 4/2 4/4	4/1 or 4/2 once a day	4/1 daily	NA	8 mg of rosiglitazone, 8 mg of glimepiride	Combination medication	Recent labeling that it may increase cardiovascular events in patients with concomitant heart failure-caution
Pioglitazone/ metformin (N)	Actoplus Met	15/500 15/850	15/500 to 15/850 once or twice daily	15/500 daily to twice daily assess renal function	NA	45 mg of pioglitazone, 2,550 mg of metformin	Combination medication	
Pioglitazone/ glimepiride (N)	Duetact	30/2 30/4	30/2 or 30/4 daily	30/2 daily to avoid hypoglycemia	NA	45 mg pioglitazone, 8 mg glimepiride	Combination Medication	Maximum dose can not be given of either medication due to formulations available
Sitagliptin/ metformin (N)	Janumet	50/500 50/1,000	50/500 twice daily with meals up to 50/1000 twice daily with meals	Either given twice daily Assess Renal Function Prior to Use	NA	100 mg sitagliptin daily	Combination Medication	Follow renal precautions for metformin
Repaglinide/ metformin (N)	Prandimet	1/500 2/500	1/500 or 2/500 2 or 3 times daily with meals	1/500 or 2/500 2 or 3 times daily with meals Assess Renal Funciton Prior to Use	NA	10 mg repaglinied, 250 mg daily of metformin	Combination Medication	Follow renal precautions for metformin. Caution drug–drug interactions with repalginide

1 DM, high fasting C-peptide levels, and moderate fasting hyperglycemia (<250 mg/dL). If glycemic goals are met, a secondary failure rate of approximately 5% to 7% per year can be expected.

Microvascular Complications. Sulfonylureas showed a reduction of microvascular complications in type 2 DM patients in the UKPDS.[32] A more in-depth discussion follows later in the chapter.

Macrovascular Complications. The UKPDS reported no significant benefit or harm in newly diagnosed type 2 DM patients given sulfonylureas over 10 years. The University Group Diabetes Program study documented higher rates of coronary artery disease in type 2 patients given tolbutamide, when compared with patients given insulin or placebo, though this study has been widely criticized.[46,47] Some sulfonylureas bind to the SUR-2A receptor that is found in cardiac tissue. Binding to the SUR-2A receptor has been implicated in blocking ischemic preconditioning via K^+ channel closure in the heart. Ischemic preconditioning is the premise that prior ischemia in cardiac tissue can provide greater tolerance of subsequent ischemia. Thus, patients with heart disease potentially have one compensatory mechanism to protect the heart from ischemia blocked. Conclusions are controversial and readers are referred to the pertinent articles for further discussion.[48–50]

Adverse Effects. The most common side effect of sulfonylureas is hypoglycemia. The pretreatment fasting plasma glucose is a strong predictor of hypoglycemic potential. The lower the FPG is upon initiation, the higher the potential for hypoglycemia. Also, in addition to the high-risk individuals outlined in the pharmacokinetics section, those who skip meals, exercise vigorously, or lose substantial amounts of weight are also more likely to experience hypoglycemia.

Hyponatremia (serum sodium <129 mEq/L) is reportedly associated with tolbutamide, but it is most common with chlorpropamide and occurs in as many as 5% of individuals treated. An increase in antidiuretic hormone secretion is the mechanism for hyponatremia. Risk factors include age >60 years, female gender, and concomitant use of thiazide diuretics.

Weight gain is common with sulfonylureas. In essence, patients who are no longer glycosuric and who do not reduce caloric intake with improvement of blood glucose will store excess calories. Other notable, although much less common, adverse effects of sulfonylureas are skin rash, hemolytic anemia, gastrointestinal upset, and cholestasis. Disulfiram-type reactions and flushing have been reported with tolbutamide and chlorpropamide when alcohol is consumed.

Drug Interactions. Several drugs are thought to interact with sulfonylureas, and Table 83–12 summarizes them by proposed mechanisms of action.[51] Drug interactions from protein-binding

TABLE 83-12 Drug Interactions with Sulfonylureas

Interaction	Drugs
Displacement from protein binding sites[a]	Warfarin, salicylates, phenylbutazone, sulfonamides
Alters hepatic metabolism (cytochrome P450)	Chloramphenicol, monoamine oxidase inhibitors, cimetidine, rifampin[b]
Altered renal excretion	Allopurinol, probenecid

[a]Many of these drug interactions may be metabolism-based.
[b]Inducer.
Reproduced from Gerich.[51]

changes should occur shortly after the interacting medication is given, as the concentration of free (thus active) sulfonylurea will acutely increase. First-generation sulfonylureas, which bind to proteins ionically, are more likely to cause drug–drug interactions than second-generation sulfonylureas, which bind nonionically.[52] The clinical importance of protein-binding interactions has been questioned, as the majority of these drug interactions have been found to be truly due to hepatic metabolism. Drugs that are inducers or inhibitors of CYP450 2C9 should be monitored carefully when used with a sulfonylurea. Additionally, other drugs known to alter blood glucose should be considered (see Table 83–10).

Dosing and Administration. The usual starting dose and maximum dose of sulfonylureas are summarized in Table 83–11. Lower dosages are recommended for most agents in elderly patients and those with compromised renal or hepatic function. The dosage should be titrated every 1 to 2 weeks (use a longer interval with chlorpropamide) to achieve glycemic goals. This is possible due to the rapid increase of insulin secretion in response to the sulfonylurea. Of note, immediate-release glipizide's maximal dose is 40 mg/day, but its maximal effective dose is about 10 to 15 mg/day. The maximal effective dose of sulfonylureas tends to be about 60% to 75% of their stated maximum dose.

Short-Acting Insulin Secretagogues ***Pharmacology.*** Though the binding site is adjacent to the binding site of sulfonylureas, nateglinide and repaglinide stimulate insulin secretion from the β cells of the pancreas, similarly to sulfonylureas. Repaglinide, a benzoic acid derivative, and nateglinide, a phenylalanine amino acid derivative, both require the presence of glucose to stimulate insulin secretion. As glucose levels diminish to normal, stimulated insulin secretion diminishes.

Pharmacokinetics. Both nateglinide and repaglinide are rapid-acting insulin secretagogues that are rapidly absorbed (~0.5–1 hour) and have a short half-life (1–1.5 hours). Nateglinide is highly protein-bound, primarily to albumin, but also to α_1-acid glycoprotein. Nateglinide is predominantly metabolized by CYP2C9 (70%) and CYP3A4 (30%) to less active metabolites. Glucuronide conjugation then allows rapid renal elimination. No dosage adjustment is needed in moderate to severe renal insufficiency. Repaglinide is highly protein bound, and is mainly metabolized by oxidative metabolism and glucuronidation. The CYP3A4 and 2C8 system have been show to be involved with metabolism. Approximately 90% of repaglinide is eliminated in the feces, with only 10% found in the urine. Moderate to severe renal insufficiency does not appear to affect repaglinide, but moderate to severe hepatic impairment may prolong exposure.

Efficacy. In monotherapy, both significantly reduce postprandial glucose excursions and reduce HbA_{1c} levels. Repaglinide, dosed 4 mg 3 times a day, when compared with glyburide in diet-treated, drug-naïve patients reduced HbA_{1c} levels less (1% vs 2.4%, from baseline, respectively).[53] Nateglinide, dosed 120 mg 3 times a day in a similar population reduced HbA_{1c} values by 0.8%.[54] The lower efficacy of these agents versus sulfonylureas should be considered when patients are >1% above their HbA_{1c} goal. These agents can be used to provide increased insulin secretion during meals, when it is needed, in patients close to glycemic goals. Also, it should be noted that addition of either agent to a sulfonylurea will not result in any improvement in glycemic parameters.

Adverse Effects. Hypoglycemia is the main side effect noted with both agents. Hypoglycemic risk appears to be less versus sulfonylureas. In part, this is due to the glucose-sensitive release of insulin. If the glucose concentration is normal, less glucose-stimulated release of insulin will occur. In two separate studies, nateglinide rates of hypoglycemia were 3% and repaglinide 15% versus glyburide and glipizide rates of 15% and 19%, respectively. Weight gain of 2 to 3 kg has been noted with repaglinide, whereas weight gain with nateglinide appears to be <1 kg.

Drug Interactions. Glycemic control and hypoglycemia should be closely monitored when glucuronidation inhibitors are given with repaglinide. Gemfibrozil, a medication used to treat hypertriglyceridemia in DM, more than doubles the half-life of repaglinide and has resulted in prolonged hypoglycemic reactions. Gemfibrozil is a potent glucuronidation inhibitor and CYP2C8 inhibitor. Trimethoprim, a CYP2C8 inhibitor, increased repaglinide levels by 60%. Nateglinide appears to be a weak inhibitor of CYP2C9 based on tolbutamide metabolism. Though no significant drug–drug interactions have been reported, caution should be used with strong CYP2C9 and CYP3A4 inhibitors.

Dosing and Administration. Nateglinide and repaglinide should be dosed prior to each meal (up to 30 minutes prior). The recommended starting dose for repaglinide is 0.5 mg in subjects with HbA_{1c} <8% or treatment-naïve patients, increased weekly to a total maximum daily dose of 16 mg (see Table 83–11). The maximal effective dose of repaglinide is likely 2 mg with each meal, as a dose of 1 mg prior to each meal provides approximately 90% of the maximal glucose-lowering effect. Nateglinide should be dosed at 120 mg prior to meals, and does not require titration. A 60-mg dose is available, but the HbA_{1c} decrement is small (0.3%–0.5%). If a meal is skipped, the medication can be skipped, and meals extremely low in carbohydrate content may not need a dose. Both agents may be used in patients with renal insufficiency, and may fit into therapy in patients in need of an insulin secretagogue but have hypoglycemia to sulfonylureas, mode to severe renal insufficiency, well-controlled diabetes, but with erratic meal schedules.

Biguanides ***Pharmacology.*** Metformin is the only biguanide available in the United States. Metformin has been used clinically for more than 50 years, and has been approved in the United States since 1995. Metformin enhances insulin sensitivity of both hepatic and peripheral (muscle) tissues. This allows for an increased uptake of glucose into these insulin-sensitive tissues. The exact mechanisms of how metformin accomplishes insulin sensitization are still being investigated, though adenosine 5′-monophosphate–activated protein kinase activity, tyrosine kinase activity enhancement, and glucose transporter 4 all play a part. Metformin has no direct effect on the β cells, though insulin levels are reduced, reflecting increases in insulin sensitivity.

Pharmacokinetics. Metformin has approximately 50% to 60% oral bioavailability, low lipid solubility, and a volume of distribution that approximates body water. Metformin is not metabolized and does not bind to plasma proteins. Metformin is eliminated by renal tubular secretion and glomerular filtration. The average half-life of metformin is 6 hours, though pharmacodynamically, metformin's antihyperglycemic effects last more than 24 hours.

Efficacy. Metformin consistently reduces HbA_{1c} levels by 1.5% to 2.0%, fasting plasma glucose levels by 60 to 80 mg/dL, and retains the ability to reduce FPG levels when they are extremely high (>300 mg/dL). The sulfonylureas' ability to stimulate insulin release from β cells at extremely high glucose levels is often impaired, a concept commonly referred to as *glucose toxicity*. Metformin also has positive effects on several components of the insulin resistance syndrome. Metformin decreases plasma triglycerides and LDL-C by approximately 8% to 15%, as well increasing HDL-C very modestly (2%). Metformin reduces levels of PAI-1 and causes a modest reduction in weight (2–3 kg). In preliminary findings, metformin may also lower the risk of pancreatic, colon, and breast cancer in type 2 DM patients. Metformin, through adenosine 5′-monophosphate–activated protein kinase activity, may act as a growth inhibitor in some cancers and help to kill cancer "stem cells," which are resistant to chemotherapy.

Microvascular Complications. Metformin (n = 342) was compared with intensive glucose control with insulin or sulfonylureas in the UKPDS. No significant differences were seen between therapies with regard to reducing microvascular complications, but the power of the study is questionable.

6 ***Macrovascular Complications.*** Metformin reduced macrovascular complications in obese subjects in the UKPDS.[55] Metformin significantly reduced all-cause mortality and risk of stroke versus intensive treatment with sulfonylureas or insulin. Metformin also reduced diabetes-related death and myocardial infarctions versus the conventional treatment arm of the UKPDS. It should be noted that the UKPDS had very few people on lipid-lowering therapy. Metformin is logical in overweight/obese patients, if tolerated and not contraindicated, as it is the only oral antihyperglycemic medication proven to reduce the risk of total mortality and is generic.

Adverse Effects. Metformin causes gastrointestinal side effects, including abdominal discomfort, stomach upset, and/or diarrhea in approximately 30% of patients. Anorexia and stomach fullness is likely part of the reason loss of weight is noted with metformin. These side effects are usually mild and can be minimized by slow titration. Gastrointestinal side effects also tend to be transient, lessening in severity over several weeks. If encountered, make sure patients are taking metformin with or right after meals, and reduce the dose to a point at which no gastrointestinal side effects are encountered. Increases in the dose may be tried again in several weeks. Anecdotally, extended-release metformin (Glucophage-XR) may lessen some of the GI side effects. Metallic taste, interference with vitamin B_{12} absorption, and hypoglycemia during intense exercise has been documented, but are clinically uncommon.

Metformin therapy rarely (3 cases per 100,000 patient-years) causes lactic acidosis. Any disease state that may increase lactic acid production or decrease lactic acid removal may predispose to lactic acidosis. Tissue hypoperfusion, such as that due to congestive heart failure, severe lung disease, hypoxic states, shock, or septicemia, via increased production of lactic acid; and severe liver disease or alcohol, via reduced removal of lactic acid in the liver, all increase the risk of lactic acidosis. The clinical presentation of lactic acidosis is often nonspecific flu-like symptoms, thus the diagnosis is usually made by laboratory confirmation of high lactic acid levels and acidosis. Metformin use in renal insufficiency, defined as a serum creatinine of 1.4 mg/dL in women and 1.5 mg/dL in men or greater, is contraindicated, as it is renally eliminated. Elderly patients, who often have reduced muscle mass, should have their glomerular filtration rate estimated by a 24 hour urine creatinine collection. If the estimated glomerular filtration rate is less than 60 mL/min, metformin should not be given. Though not recommended to be clinically implemented, recent evidence has reported that metformin may not accumulate in moderate to severe renal insufficiency, if a dose of 1,500 mg/day or less is used. Due to the risk of acute renal failure during intravenous dye procedures, metformin therapy should be withheld starting the day of the procedure and resumed in 2 to 3 days, after normal renal function has been documented.

Drug Interactions. Cimetidine competes for renal tubular secretion of metformin and concomitant administration leads to higher metformin serum concentrations. At least one case report of lactic acidosis with metformin therapy implicates cimetidine. Theoretically other cationic drugs may interact, but none have been reported to date.[56]

Dosing and Administration. Immediate-release metformin is usually dosed 500 mg twice a day with the largest meals to minimize gastrointestinal side effects. Metformin may be increased by 500 mg weekly until glycemic goals or 2,500 mg/day is achieved (see Table 83–11). Metformin 850 mg may be dosed daily, and then increased every 1 to 2 weeks to the maximum dose of 850 mg 3 times a day (2,550 mg/day). Approximately 80% of the glycemic-lowering effect may be seen at 1,500 mg, and 2,000 mg/day is the maximal effective dose.

Extended-release metformin can be initiated at 500 mg a day with the evening meal and titrated weekly by 500 mg as tolerated to a single evening dose of 2,000 mg/day. Extended-release metformin 750 mg tablets may be titrated weekly to the maximum dose of 2,250 mg/day, though as stated above, 1,500 mg/day provides the majority of the glycemic-lowering effect. Twice daily to 3 times a day dosing of extended-release metformin may help to minimize gastrointestinal side effects and improve glycemic control.

Thiazolidinediones ***Pharmacology.*** Thiazolidinediones are also referred to as TZDs or glitazones. Pioglitazone (Actos) and rosiglitazone (Avandia) are the two currently approved thiazolidinediones for the treatment of type 2 DM (see Table 83–11). Thiazolidinediones work by binding to the peroxisome proliferator activator receptor-γ (PPAR-γ), which are primarily located on fat cells and vascular cells. The concentration of these receptors in the muscle is very low; thus this is unlikely to be the main site of action. Thiazolidinediones enhance insulin sensitivity at muscle, liver, and fat tissues indirectly. Thiazolidinediones cause preadipocytes to differentiate into mature fat cells in subcutaneous fat stores. Small fat cells are more sensitive to insulin and more able to store free fatty acids. The result is a flux of free fatty acids out of the plasma, visceral fat, and liver into subcutaneous fat, a less insulin-resistant storage tissue. Muscle intracellular fat products, which contribute to insulin resistance, also decline. TZDs also effect adipokines, (e.g., angiotensinogen, tissue necrosis factor-α, interleukin 6, plasminogen activator inhibitor 1) which can positively affect insulin sensitivity, endothelial function, and inflammation. Of particular note, adiponectin is reduced with obesity and/or diabetes, but is increased with TZD therapy, which improves endothelial function, insulin sensitivity, and has a potent antiinflammatory effect. Lastly, TZDs appear to improve mitochondrial function through a reduction in free fatty acids. Cyclin-dependent kinase 5 has also recently been purposed as an important activator of PPAR-γ.

Pharmacokinetics. Pioglitazone and rosiglitazone are well absorbed with or without food. Both are highly (>99%) bound to albumin. Pioglitazone is primarily metabolized by CYP2C8, a lesser extent by CYP3A4 (17%), and by hydroxylation/oxidation. The majority of pioglitazone is eliminated in the feces. Rosiglitazone is metabolized by CYP2C8, and to a lesser extent by CYP2C9, and also by *N*-demethylation and hydroxylation. Two-thirds is found in urine and one-third in feces. The half-lives of pioglitazone and rosiglitazone are 3 to 7 hours and 3 to 4 hours, respectively. Two active metabolites of pioglitazone with longer half-lives deliver the majority of activity at steady state. Pioglitazone requires no dosage adjustment in moderate to severe renal disease for pharmacokinetic reasons. Interestingly, with pioglitazone the AUC in women is 20% to 60% higher, which is not seen with rosiglitazone, but no dosage adjustment is recommended. Both medications have a duration of antihyperglycemic action of over 24 hours.

Efficacy. Pioglitazone and rosiglitazone, given for about 6 months, reduce HbA_{1c} values ~1.5% and reduce FPG levels by ~60 to 70 mg/dL at maximal doses. Glycemic-lowering onset is slow, and maximal glycemic-lowering effects may not be seen until 3 to 4 months of therapy. It is important to inform patients of this fact and that they should not stop therapy even if minimal glucose lowering is initially encountered. The efficacy of both drugs is dependent on sufficient insulinemia. If there is insufficient endogenous insulin production (β-cell function) or exogenous insulin delivery via injections, neither will lower glucose concentrations efficiently. Interestingly, patients who are more obese, or who gain weight on

either medication tend to have a larger reduction in HbA_{1c} values. Pioglitazone consistently decreases plasma triglyceride levels by 10% to 20%, whereas rosiglitazone tends to have a neutral effect. LDL-C concentrations tend to increase with rosiglitazone 5% to 15%, but do not significantly increase with pioglitazone. Both appear to convert small, dense LDL particles, which have been shown to be highly atherogenic, to large, fluffy LDL particles that are less dense. Large, fluffy LDL particles may be less atherogenic, but any increase in LDL must be of concern. Both drugs increase HDL similarly, up to 3 to 9 mg/dL. Thiazolidinediones also affect several components of the insulin resistance syndrome. PAI-1 levels are decreased, and many other adipocytokines are affected, endothelial function improves, and blood pressure may decrease slightly.

Microvascular Complications. Thiazolidinediones reduce HbA_{1c} levels, which have been shown to be related to the risk of microvascular complications.

Macrovascular Complications. Macrovascular complications with thiazolidinediones are controversial. In PROactive, the prospective pioglitazone clinical trial in macrovascular events, pioglitazone 45 mg was added to standard therapy in patients who had experienced a macrovascular event or had peripheral vascular disease.[57] The two groups were well matched at baseline and the reported average observation time period was about 3 years. The primary endpoint (reduction in death, myocardial infarction, stroke, acute coronary syndrome, coronary revascularization, leg amputation, and leg revascularization) was reduced 10% ($P = 0.095$). The main secondary endpoint (all-cause mortality, nonfatal myocardial infarction, or stroke) was reduced 16% ($P = 0.027$). The seemingly dichotomous results relate to the inclusion of leg revascularization as a primary endpoint, which were increased in the pioglitazone group. Reasons for the increase are speculative, but may relate to more testing/inspection due to peripheral edema. Also of note, the pioglitazone group had 209 nonadjudicated admissions for heart failure occur versus 153 in the placebo group ($P = 0.007$), though fatal heart failure was not increased. Several published meta-analysis of rosiglitazone reported higher myocardial infarction (MI) rates with rosiglitazone, but none have reported a higher risk of mortality. A hazard ratio (HR) of 1.43 (95% confidence interval [CI], 1.03–1.98; $P = 0.03$) for the risk of an MI with rosiglitazone versus other oral agents was reported.[58] A prospective, multicenter, open-label noninferiority trial in 4,447 patients of rosiglitazone added to background metformin or sulfonylurea versus the active comparator metformin + sulfonylurea was recently reported (Rosiglitazone Evaluated for Cardiovascular Outcomes in Oral Agent Combination Therapy for Type 2 Diabetes [RECORD]). Rosiglitazone was noninferior to the comparator for all CV outcomes except for heart failure. A nonsignificant increase in risk for MI (HR, 1.14; 95% CI, 0.80–1.63) as well as a nonsignificant reduction in stroke (HR, 0.72; 95% CI, 0.49–1.05) was reported. On subset analysis, previous ischemic heart disease trended toward a higher risk (HR, 1.26; CI, 0.95–1.68; $P = 0.055$). Questions still linger about the study being underpowered and certain subsets of subjects taken off rosiglitazone when given insulin; but RECORD, the only study to look at CVD risk prospectively with rosiglitazone, was neutral.[59]

CLINICAL CONTROVERSY

At a minimum, antihyperglycemic drugs should be neutral on cardiovascular events, because the majority of people with diabetes die from CVD. Both pioglitazone and rosiglitazone, equally, can result in pulmonary edema and/or heart failure, and using them with insulin or in people with preexisting heart failure may increase the incidence. TZD-related congestive heart failure is not associated with a higher risk of mortality. Several meta-analyse have reported an increased risk of MI with the use of rosiglitazone. In the randomized, prospective RECORD trial, rosiglitazone was noninferior to the comparator for all CV outcomes except for heart failure. In contrast, no study has shown an increased risk for MI with pioglitazone, and in PROactive, there was a significant 16% reduction in the combined endpoint of mortality, MI, and stroke. Overall, prospective evidence to date shows TZDs to be neutral on CVD risk except for heart failure, with a potential lowering of CVD risk with pioglitazone.

Adverse Effects. Troglitazone, the first thiazolidinedione approved, caused idiosyncratic hepatotoxicity and had 28 deaths from liver failure, which prompted removal from the U.S. market in March 2000. Approximately 1.9% of patients placed on troglitazone had alanine aminotransferase (ALT) levels more than 3 times the upper limit of normal. The incidence, using these criteria for elevated liver enzymes, with pioglitazone (0.25%) and rosiglitazone (0.2%) has been low. No evidence of hepatotoxicity was reported in an analysis of more than 5,000 patients given rosiglitazone or pioglitazone.[60] Several case reports of hepatotoxicity with rosiglitazone or pioglitazone have been reported, but improvement in ALT was consistently noted when the drug was discontinued. Prior to therapy, it is recommended that an ALT be checked, and periodically after at the practitioner's discretion. Patients with ALT levels >2.5 times the upper limit of normal should not start either medication, and if the ALT is >3 times the upper limit of normal the medication should be discontinued.

Retention of fluid leads to many different possible side effects with rosiglitazone and pioglitazone. The etiology of the fluid retention has not been fully elucidated, but appears to include peripheral vasodilation and/or improved insulin sensitization at the kidney with a resultant increase in renal sodium and water retention. A reduction in plasma hemoglobin (2%–4%), attributed to a 10% increase in plasma volume, may result in a dilutional anemia which does not require treatment. Edema is also commonly (4%–5% in mono- or combination therapy) reported. When a thiazolidinedione is used in combination with insulin, the incidence of edema (~15%) is increased. Thiazolidinediones are contraindicated in patients with New York Heart Association Class III and IV heart failure, and great caution should be exercised when given to patients with Class I and II heart failure or other underlying cardiac disease, as pulmonary edema and heart failure have been reported. Edema tends to be dose related and if not severe, a reduction in the dose as well as use of diuretics, anecdotally hydrochlorothiazide with triamterene, amiloride, or spironolactone instead of loop diuretics, will allow the continuation of therapy in the majority of patients.[61] Rarely, thiazolidinediones have been reported to worsen macular edema of the eye.

Weight gain, which is also dose related, can be seen with both rosiglitazone and pioglitazone. Mechanistically, both fluid retention and fat accumulation play a part in explaining the weight gain. Thiazolidinediones, besides stimulating fat cell differentiation, also reduce leptin levels, which stimulate appetite and food intake. Average weight gain varies, but a 1.5- to 4-kg weight gain is not uncommon. Rarely, a patient will gain large amounts of weight in a short period of time, and this may necessitate discontinuation of therapy. Weight gain positively predicts a larger HbA_{1c} reduction, but must be balanced with the well-documented effects of long-term weight gain.

Thiazolidinediones have also been associated with an increased fracture rate in the upper and lower limbs in women and men, though women appear to have a higher risk. These fractures are not osteoporitic in the classic sense, and do not occur in common osteoporosis fracture sites such as spine or hip. Most occur in wrists, forearms, ankles, or feet. Versus comparative diabetes therapy, thiazolidinediones may increase the risk of a fracture by 25%. The underlying pathophysiology is speculative, but may relate

to thiazolidinediones effect on the pluripotent stem cell and shunting of new cells to fat instead of osteocytes. It would be prudent to consider a patient's risk factors for fractures if a thiazolidinedione is being considered as antidiabetic therapy.

As a caution, premenopausal anovulatory patients may resume ovulation on thiazolidinediones. Adequate pregnancy and contraception precautions should be explained to all women capable of becoming pregnant, as both agents are pregnancy category C.

Drug Interactions. Significant drug interactions that can cause clinical sequelae have not been noted with either medication. Neither pioglitazone nor rosiglitazone appear to be inhibitors or inducers of CYP3A4/2C8 or CYP2C8/CYP2C9, respectively, though drugs that are strong inhibitors or inducers of these pathways (e.g., gemfibrozil or rifampin) may increase or decrease levels of active drug significantly.

Dosing and Administration. The recommended starting dosages of pioglitazone and of rosiglitazone are 15 to 30 mg once daily and 2 to 4 mg once daily, respectively. Dosages may be increased slowly based on therapeutic goals and side effects. The maximum dose and maximum effective dose of pioglitazone is 45 mg, and rosiglitazone is 8 mg once daily, though 4 mg twice a day may reduce HbA_{1c} by 0.2% to 0.3% more versus 8 mg once daily.

α-Glucosidase Inhibitors

Pharmacology. Currently, there are two α-glucosidase inhibitors available in the United States acarbose (Precose) and miglitol (Glyset). α-Glucosidase inhibitors competitively inhibit enzymes (maltase, isomaltase, sucrase, and glucoamylase) in the small intestine, delaying the breakdown of sucrose and complex carbohydrates.[62,63] They do not cause any malabsorption of these nutrients. The net effect from this action is to reduce the postprandial blood glucose rise.

Pharmacokinetics. The mechanism of action of α-glucosidase inhibitors is limited to the luminal side of the intestine. Some metabolites of acarbose are systemically absorbed and renally excreted, whereas the majority of miglitol is absorbed and renally excreted unchanged.

Efficacy. Postprandial glucose concentrations are reduced (40–50 mg/dL), while fasting glucose levels are relatively unchanged (~10% reduction). Efficacy on glycemic control is modest (average reductions in HbA_{1c} of 0.3%–1%), affecting primarily postprandial glycemic excursions. Thus, patients near target HbA_{1c} levels with near-normal fasting plasma glucose levels, but high postprandial levels, may be candidates for therapy.

Microvascular Complications. α-Glucosidase inhibitors modestly reduce HbA_{1c} levels, which has been shown to be related to the risk of microvascular complications.

Macrovascular Complications. The STOP-NIDDM study, in subjects with impaired glucose tolerance, reported a significant reduction in the risk of cardiovascular events, though the total number of events were small.[64,65] No large cardiovascular study confirming these preliminary results has been done in prediabetes or diabetes patients.

Adverse Effects. The gastrointestinal side effects, such as flatulence, bloating, abdominal discomfort, and diarrhea, are very common and greatly limit the use of α-glucosidase inhibitors. Mechanistically, these side effects are caused by distal intestinal degradation of undigested carbohydrate by the microflora, which results in gas (CO_2 and methane) production. Microflora convert the carbohydrate to short-chain fatty acids which are mostly absorbed, thus there is not a large calorie loss. α-Glucosidase inhibitors should be initiated at a low dose and titrated slowly to reduce gastrointestinal intolerance. Beano, an α-glucosidase enzyme, may help to decrease gastrointestinal side effects, but may decrease efficacy slightly, and it is better to decrease carbohydrate or the dose of the α-glucosidase inhibitor.[66]

If a patient develops hypoglycemia within several hours of ingesting an α-glucosidase inhibitor, oral glucose is advised because the drug will inhibit the breakdown of more complex sugar molecules. Milk, with lactose sugar, may be used as an alternative when no glucose is available, as acarbose only slightly (10%) inhibits lactase.

Rarely, elevated serum aminotransferase levels have been reported with the highest doses of acarbose. It appeared to be dose and weight related, and is the premise for the weight-based maximum doses.

Dosing and Administration. Dosing for both miglitol and acarbose are similar. Initiate with a very low dose (25 mg with one meal a day); increase very gradually (over several months) to a maximum of 50 mg 3 times a day for patients ≤60 kg or 100 mg 3 times a day for patients >60 kg (see Table 83–11). Titration speed should be varied based on gastrointestinal side effects to the target dose. Both α-glucosidase inhibitors should be taken with the first bite of the meal so that drug may be present to inhibit enzyme activity. Only patients consuming a diet high in complex carbohydrates will have significant reductions in glucose levels. α-Glucosidase inhibitors are contraindicated in patients with short-bowel syndrome or inflammatory bowel disease, and neither should be administered in patients with serum creatinine >2 mg/dL, as this population has not been studied.

Dipeptidyl Peptidase 4 Inhibitors (DPP-4 Inhibitors)

Sitagliptin (Januvia) and saxagliptin (Onglyza) are the two DPP-4 inhibitors currently approved in the United States.

Pharmacology. DPP-4 inhibitors prolong the half-life of endogenously produced GLP-1 and glucose-dependent insulinotopic polypeptide (GIP) which is normally only minutes. GIP levels are normal in type 2 DM, and may contribute a minor amount of insulin secretion but have no effect on glucagon. It has clearly been shown that GLP-1 levels are deficient in type 2 DM. As these agents block nearly 100% of the DPP-4 enzyme activity for at least 12 hours, normal physiologic, nondiabetic GLP-1 levels are achieved. DPP-4 inhibitors significantly reduce the inappropriately elevated glucagon postprandially, though not back to nondiabetic levels, and improve insulin response to a high glucose level. Insulin levels tend to be unchanged with DPP-4 inhibitors, but glucose levels are reduced. This is an improvement in insulin secretion, as a nondiabetic person would decrease insulin secretion in response to the lower glucose readings. These drugs do not alter gastric emptying or have significant satiety effects.

Pharmacokinetics. Sitagliptin appears to have rapid absorption, with a t_{max} of approximately 1.5 hours. Absolute bioavailability after oral intake is approximately 87%. Only ~40% is bound to plasma proteins, and the volume of distribution is approximately 200 liters. The $t_{1/2}$ of sitagliptin is approximately 12 hours, and 79% of the dose of sitagliptin is excreted unchanged in the urine by active tubular secretion, though the organic anion transporter 3 or p-glycoprotein transport may be involved as well. Sitagliptin exposure is increased by approximately 2.3-, 3.8-, and 4.5-fold relative to healthy subjects for patients with moderate renal insufficiency (creatinine clearance [CL_{cr}] 30 to <50 mL/min), severe renal insufficiency (CL_{cr} <30 mL/min), and ESRD (on dialysis), respectively. Though not a safety or adverse reaction issue, reduction of the dose based on renal function is appropriate, as only 100% of the enzyme can be inhibited, and long-term exposure to higher levels in humans has not been extensively studied. Pharmacodynamically, DPP-4 inhibition appeared to mirror directly the plasma concentration of sitagliptin. Doses of 50 mg produced at least 80% inhibition of DPP-4 enzyme activity at 12 hours, and 100 mg produced 80% inhibition of DPP-4 enzyme activity at 24 hours. Food had no effect on absoption kinetics of sitagliptin, and hepatic impairment, age, gender, or race had no effect on the pharmacokinetics.

The t_{max} increased about 20 minutes and the AUC increased about 27% when saxagliptin was administered with a high-fat meal, though saxagliptin may be given with or without meals. The oral bioavailability of saxagliptin is approximately 67%. Distribution is similar to the body water compartment. There is negligible protein binding, and one active metabolite, 5-hydroxy saxagliptin, which is half as potent a DPP-4 inhibitor as the parent compound, and contributes to activity. Metabolism is by the CYP3A4/5 system, and strong inhibitors or inducers will have an effect on activity. The half-life of saxagliptin and its active metabolite are 2.5 hours and 3.1 hours, respectively. Approximately 25% of the dose is found in feces representing unabsorbed drug and bile excretion. No accumulation was noted with saxagliptin or its active metabolite. Females have ~25% more exposure to 5-hydroxy saxagliptin, and exposure is increased 25% to 50% in elderly, likely due to renal clearance. The majority (75%) of saxagliptin and 5-hydroxy saxagliptin is renally eliminated, and some renal excretion is seen. In moderate (CL_{cr} 30–50 mL/min) or severe (CL_{cr} <30 mL/min) renal impairment, saxagliptin and its active metabolite exposure are increased 2.1- and 4.5-fold, respectively.

Efficacy. The average reduction in HbA_{1c} with sitagliptin or saxagliptin is approximately 0.7% to 1% at maximum dose. The HbA_{1c} decrement is dependent on the baseline value, with a larger reduction being seen with a higher baseline HbA_{1c}. As they are well tolerated, adjustment in the dose for adverse effects is unlikely.

Microvascular and Macrovascular Complications. HbA_{1c} levels are reduced, which has been related to a reduction in microvascular complications, but no outcome data are available to date.

Drug–Drug Interactions. Significant drug–drug interactions with sitaglitin are unlikely. Sitagliptin is metabolized approximately 20% by CYP450 3A4 with some CYP450 2C8 involvement, but is neither an inhibitor nor inducer of any CYP450 enzyme system. Sitagliptin is a p-glycoprotein substrate, but had negligible effects on digoxin and cyclosporine A, increasing the AUC by only 30%.

Saxagliptin is metabolized by CYP3A4/5, and is a substrate for p-glycoprotein substrate, but is neither an inhibitor nor inducer. Rifampin, an inducer, can decrease active levels by 50%. Moderate to strong inhibitors or inducers of CYP3A4/5, such as diltiazem or ketoconazole, can increase the AUC of saxagliptin by approximately 2-fold, with a corresponding decrease in the formation of the active metabolite 5-hydroxy saxagliptin. It is recommended that the dose of saxagliptin be limited to 2.5 mg daily if a stronger inhibitor is used.

Adverse Effects. Both drugs are very well tolerated, weight neutral, and do not cause gastrointestinal side effects. Mild hypoglycemia may occur, but in monotherapy or in combination with medication that have a low incidence of hypoglycemia, DPP-4 inhibitors do not increase the risk of hypoglycemia. Headache and nasopharyngitis, potentially related to the drug, may be slightly more common with DPP-4 inhibitors, but no significant increases in peripheral edema, hypertension, or cardiac outcomes have been noted to date.

Uticaria and/or facial edema may be seen in approximately 1% of patients, and discontinuation is warranted. Rare cases of Stevens-Johnson syndrome have been reported.

In regard to long-term safety, DPP-4 enzymes metabolize a wide variety of peptides (PYY, neuropeptide Y, growth hormone-releasing hormone, vasoactive intestinal polypeptide, and others) potentially affecting other regulatory systems. DPP-4 (also known as CD26) plays an important role for T-cell activation and theoretically the inhibition of DPP-4 could be associated with adverse immunologic reactions. Saxagliptin results in a dose-related reduction in absolute lymphocyte count. Approximately 1.5% of patients had a count less than 750 cells/microliter, and discontinuation/rechallenge was confirmed in some patients. The clinical relevance is not known, but if prolonged infection is encountered, it is logical to measure lymphocyte counts and consider discontinuation.

Additionally DPP-8/9 inhibition in animals produced multiple toxicities. Sitagliptin is more selective for DPP-4 than DPP-8/9 (>2,600-fold). Saxagliptin and its active metabolite 5-hydroxy saxagliptin are more specific for DPP-4 than DPP-8 (400- and 950-fold) and DPP-9 (75- and 160-fold), respectively.

Dosing and Administration Sitagliptin is dosed orally at 100 mg daily unless renal insufficiency is present. The 50-mg dose is recommended if the creatinine clearance is 30 to less than 50 mL/min, or 25 mg if less than 30 mL/min. Equivalent serum creatinine levels are as follows: sitagliptin 50 mg daily in men, greater than 1.7 to 3.0 mg/dL, women, greater than 1.5 to 2.5 mg/dL; 25 mg daily in men, greater than 3.0 mg/dL, women, greater than 2.5 mg/dL. Saxagliptin is dosed orally 5 mg daily, unless the creatinine clearance is less than 50 mL/min, or strong CYP3A4/5 inhibitors are used, then the recommended daily dose is 2.5 mg. Because of their excellent tolerability profile and a fairly flat dose-response curve, these drugs should be maximally dosed, unless noted above.

Bile Acid Sequestrants

Currently, the only bile acid sequestrant approved for the treatment of type 2 DM is colesevelam (Welchol).

Pharmacology. Colesevelam is a bile acid sequestrant which acts in the intestinal lumen to bind bile acid, decreasing the bile acid pool for reabsorption. Whether colesevelam's mechanism of action to lower plasma glucose levels is in the intestinal lumen, a systemic effect due to the intestinal lumen effect or some combination of these two is unknown.

Pharmacokinetics. Colesevelam is not absorbed from the intestinal lumen, thus there is not absorption, distribution, or metabolism.

Efficacy. HbA_{1c} reductions from baseline (~8.0%) were approximately 0.4% when a dose of 3.8 g/day was added to stable metformin, sulfonylureas, or insulin. The fasting plasma glucose was modestly reduced about 5 to 10 mg/dL. Colesevelam may also reduce LDL-C cholesterol. A 12% to 16% reduction in LDL-C was reported with type 2 DM and a baseline LDL-C concentrations of ~105 mg/dL. Triglycerides increased when combined with sulfonylureas or insulin, but not with metformin. Colesevelam is weight neutral. Pediatric patients (10–17 years of age) have been studied for cholesterol reduction, but not for type 2 DM.

Microvascular Complications. Bile acid sequestrants modestly reduce HbA_{1c} levels, which have been shown to be related to the risk of microvascular complications.

Macrovascular Complications. Though colesevelam lowers plasma glucose and LDL-C, it has not been proven to prevent cardiovascular morbidity or mortality.

Drug–Drug Interactions. There are multiple absorption related drug–drug interactions with colesevelam. Tables 83–13, 83–14, and 83–15 summarizes medications that may interact with colesevelam. It is recommended that medications suspected of an interaction should be moved at least 4 hours prior to dosing the colesvelam. Colesevelam has also been implicated in the malabsorption of fat-soluable vitamins (A, E, D, K). In addition to the obvious fat-soluable vitamin supplementation, this may have implications for associated conditions. Other drugs that are very fat soluable such as cyclosporine A, drugs that may be affected by a change in fat-soluable vitamin status such as warfarin and vitamin K, or conditions that may that may be potentially worsened by fat-soluable vitamin status such as some bleeding disorders or dermatologic conditions should be monitored.[67]

Adverse Effects. The most common side effects are gastrointestinal. Constipation (11%) and dyspepsia (8%) are more common with colesevelam than placebo. Because of the constipating effects of

TABLE 83-13 Drugs with Known Interactions

Levothyroxine
Glyburide
Oral contraceptives with ethinyl estradiol and norethindrone

colesevelam, it is not recommended in patients with gastroparesis, bowel obstruction, or a history of major gastrointestinal surgery. It also should not be used in patients with significant swallowing or esophageal issues, as it may worsen the underlying condition or cause obstruction. Colesevelam should be taken with a large amount of water to lower the risk of the above issues. Hypoglycemia rates were low, though caution with insulin or sulfonylureas is prudent.

Colesevelam, similar to all bile acid sequestrants, may raise triglyceride levels. The increase in triglycerides is proportional to baseline triglyceride levels, and colesevelam is contraindicated in patients with a triglyceride >500 mg/dL. Close monitoring is recommended if the baseline triglycerides greater than 300 mg/dL. Colesevelam is contraindicated in patients with a history of triglyceridemia induced pancreatitis, and prudent clinical judgement should be used in any patient with a history of pancreatitis and elevated triglycerides.

Dosing and Administration. Dosing for type 2 DM is six 625-mg tablets daily (total dose/day = 3.75 g), which may be split into 3 tablets 2 times a day if desired. A 3.75-g oral suspension packet, dosed daily, or a 1.875-g oral suspension packet dose twice daily is also available. Suspension packets must be diluted in a minimum of one-half to 1 cup of water. Take tablets and suspension with a large amount of water, if possible. All dosage forms should be administered with meals as colesevelam binds to bile released during the meal.

Dopamine Agonists Bromocriptine mesylate (Cycloset) is currently approved for the treatment of type 2 DM, but is not commercially available at the time this chapter was written.

Pharmacology. Bromocriptine is a dopamine agonist, but the exact mechanism of how bromocriptine improves glycemic control is unknown. In vertebrates, oscillations in neurotransmitters, including dopamine, can change the response to insulin, and animal and human data indicate that bromocriptine administered in the morning improves insulin sensitivity.

Pharmacokinetics. Bioavailability is 65% to 95% after an orally administered dose, bioavailability may be increased ~50% if given with a meal. Bromocriptine is highly protein bound, and has a volume of distribution of 61 liters. Only ~7% reaches the systemic circulation due to gastrointestinal-based metabolism and first-pass metabolism. Bromocriptine is extensively metabolized by the CYP3A4 pathway, and the majority (~95%) is excreted in the bile. The half-life is approximately 6 hours. Plasma exposure is increased in females by approximately 18% to 30%, but no dosage adjustment is currently recommended.

Efficacy. In clinical trials, bromocriptine mesylate reduced HbA_{1c} by a modest 0.1% to 0.4% from baseline (HbA_{1c} 8%–9%).

Microvascular and Macrovascular Complications. It is unclear what effect, if any, bromocriptine may have on outcomes, though no increase in cardiovascular event signal was detected from data presented to the FDA.

Drug–Drug Interactions. Bromocriptine is extensively metabolized by CYP3A4 and strong inhibitors or inducers may change bromocriptine levels. As bromocriptine is highly protein bound, it may increase the unbound fraction of other highly protein bound drugs. Several drug–drug and potential drug–disease interactions are present including antipsychotics in psychotic disorders as they decrease dopamine activity, atypical antipsychotics, as they may decrease the effectiveness of bromocriptine, and ergot-based therapy for migraines as bromocriptine may increase migraine and ergot related nausea and vomiting. There are case reports of hypertension and tachycardia when administered with sympathomimetic drugs in postpartum women, and bromocriptine should not be given to this group of potential patients. The effectiveness in other disease states where dopamine agonism may be indicated is unknown.

Adverse Effects. Adverse reactions leading to discontinuation occurred in 24% of bromocriptine patients compared to 9% in the placebo comparator group. Nausea, rhinitis, headache, asthenia, dizziness, constipation, and sinusitis all occurred in over 10% of subjects. Nausea occurred in 25% to 35% of patients, and vomiting, which tended to be more common in women, occurred in 5% to 6% of patients. Nausea, vomiting, fatigue, headache, and dizziness were common adverse events during the titration phase of phase 3 studies, and only 70% of completors could be titrated to the maximum dose. Orthostatic hypotension or syncope occurred in 2.2% and 1.4%, and 0.6% and 0.8% in the bromocriptine and placebo groups, respectively. No predisposing factors were identified, but caution should be exercised in patients with low, normal blood pressure. Somnolence was reported in 4.3% of patients on bromocriptine, compared with 1.3% in the placebo, and response to the drug should be ascertained prior to operating machinery or combining with other sedating medications. Psychiatric disorders including hallucinations and pathological gambling have been reported with other forms of bromocriptine, but were not seen in phase III trials.

Dosing and Administration. Bromocriptine is dosed with 0.8-mg tablets administered within 2 hours of waking from sleep daily. From 0.8 mg daily, the dose may be increased weekly based on response by 0.8-mg tablet increments, to a maximum of 4.8 mg daily (0.8 mg × 6 tablets, though it is unclear if another commercial dose could be made available). The minimal effective dose is 1.6 mg daily.

POTENTIAL FUTURE MEDICATIONS

Many medications for the treatment of diabetes are currently in late-phase development. No guarantee of FDA approval is given for any agent in development.

Exenatide Long-Acting-Release (Bydureon)

A once-weekly, long-acting injection preparation of the current twice-daily exenatide formulation is being developed. Exenatide is embedded in small beads of material similar to absorbable suture material. This allows for the embedded exenatide to be released over 1 week. Data out to 1 year has shown better FPG and HbA_{1c} lowering than the current twice daily exenatide. Safety and side effects, with slightly less nausea with the weekly preparation, appears similar to twice daily exenatide.

Other Incretin Class Medications

Several other DPP-4 inhibitors may be approved, including alogliptin, dutogliptin, and linagliptin. There will likely be many DPP-4 inhibitors on the market soon. Taspoglutide, a once-weekly human analog GLP-1 agonist may also be approved in the next several years. Taspoglutide dosing is speculative, but will likely be 20 to 30 mg weekly.

Selective Sodium-dependent Glucose Cotransporter-2 Inhibitors (SGLT-2 Inhibitors)

SGLT-2 inhibitors works in the kidney to block the reabsorption of some glucose. Normally, all glucose is reabsorbed back into the systemic circulation from the kidney at normal glucose levels; about 10% through the SGLT-1 receptor, and 90% through the SGLT-2 receptor. Early data has shown approximately 50 to 80 grams of glucose per day may be allowed to pass into the urine with SGLT-2 inhibition. This lowers systemic glucose and allows weight loss. Glucose levels may be lowered in both type 1 and type 2 DM by this mechanism of action. Safety data has shown a slightly higher rate of genitourinary yeast infections to date. SGLT-1 is involved with glucose absorption in the gut, and selectivity is important, as inhibition of SGLT-1 may cause gastrointestinal toxicity. Dapagliflozin is currently the farthest in development, but several are being developed.

PIVOTAL TRIALS

Diabetes Control and Complications Trial

7 Much of the last century in diabetes care was dominated by the debate over whether glycemic control actually was causative in complications of DM. Animal studies and some human studies suggested that the worse the glycemia the greater the risk of complications. But "the glucose hypothesis" was not ultimately accepted as proven until the publication of the DCCT in 1993.[31] In this study, 1,441 patients with type 1 DM were divided into two groups: those without complications (726 subjects, primary prevention), and those with early microvascular complications (715 subjects, secondary prevention). These two groups were then again divided into two groups, one randomized to receive conventional therapy (one or two shots of insulin daily and infrequent SMBG with no attempt to change therapy based on home blood glucose readings), and the other to receive intensive therapy (3+ injections of insulin daily or insulin pump, with frequent SMBG and alteration of insulin therapy based on SMBG results, plus frequent contact with a health professional). After 6.5 years, mean follow-up with a difference in HbA_{1c} between the two groups being ≈2% (≈9% vs ≈7%), retinopathy was decreased by 76% in the primary prevention cohort, with retinopathy progression reduced 54% in the secondary prevention group. Neuropathy was decreased by 60% in both groups combined. Microalbuminuria was decreased 39%, while macroproteinuria was reduced 54% with intensive therapy. Hypoglycemia was more common and weight gain greater with intensive therapy. A nonstatistically significant reduction in coronary events was seen in the intensively treated group as compared with the conventional group. The DCCT revolutionized therapy of DM, demanding that stricter glycemic control be the goal.

United Kingdom Prospective Diabetes Study

The UKPDS was a landmark study for the care of patients with type 2 DM, confirming the importance of glycemic control for reducing the risk of microvascular complications.[32] More than 5,000 patients with newly diagnosed type 2 DM were entered into the study. Patients were followed for an average of 10 years. The major portion of the study assessed "conventional therapy" (no drug therapy unless the patient was symptomatic or had FPG >270 mg/dL), versus intensive therapy starting with either sulfonylureas or insulin, aimed at keeping the fasting plasma glucose <108 mg/dL. A subset of obese patients was studied using metformin as the primary therapeutic agent.

CLINICAL CONTROVERSY

Preservation of β-cell function, and thus arresting the progression of type 2 diabetes, is an important secondary goal after glycemic control. The UKPDS clearly showed that sulfonylureas, metformin, and insulin are ineffective in stopping the progressive β-cell failure. In animal models, TZDs, exenatide, and DPP-4 inhibitors have been able to arrest β-cell failure. In humans, durability of HbA_{1c} reduction and β-cell function is improved with TZDs and GLP-1 agonists. These medications have shown to slow, through durable HbA_{1c} reduction, but not to arrest the progressive β-cell decline in type 2 DM. Monotherapy with these medications will not likely succeed in fully arresting HbA_{1c} deterioration over time, and only combination therapy, with drugs such as TZDs and GLP-1 agonists, may accomplish this, though long-term data are lacking.

Significant findings from the study include the following:

- Microvascular complications (predominantly the need for laser photocoagulation on retinal lesions) are reduced by 25% when median HbA_{1c} is 7% as compared with 7.9%.[32]
- A continuous relationship exists between glycemia and microvascular complications, with a 35% reduction in risk for each 1% decrement in HbA_{1c}. No glycemic threshold for microvascular disease exists.[68]
- Glycemic control has minimal effect on macrovascular disease risk.[62] Excess macrovascular risk appears to be related to conventional risk factors such as dyslipidemia and hypertension.[69]
- Sulfonylureas and insulin therapy do not increase macrovascular disease risk.[32]
- Metformin reduces macrovascular risk in obese patients.[55]
- Vigorous blood pressure control reduces microvascular and macrovascular events.[69] There was no evidence for a threshold systolic blood pressure above 130 mm Hg for protection against complications. β-Blockers and ACE inhibitors appear to be equally efficacious.[70]

Long-Term Follow-Up of DCCT (EDIC) and UKPDS

At the conclusion of the DCCT and UKPDS trials, willing subjects continued to be followed over time to ascertain micro- and macrovascular outcomes. In the follow-up of the DCCT, called the Epidemiology of Diabetes Interventions and Complications (EDIC), several important points have been discovered. First, HbA_{1c} levels between conventional and intensive groups converged to a HbA_{1c} of

approximately 8%. Despite similar HbA_{1c} values, continued micro- and new macrovascular benefit was seen. Microvascular benefits were maintained for 10 to 15 years, and at 17 years of follow-up, a 57% ($P = 0.02$) reduction in death, first occurance of nonfatal MI and stroke was seen between the conventional and intensive groups.[71,72]

In the follow-up of the UKPDS, HbA_{1c} (~8%) converged and values were not significantly different for the majority of the follow-up. After a mean follow-up of 8.5 years, a 24% ($P = 0.001$) reduction in microvascular complications (during the UKPDS, 25% reduction was reported) and a significant reduction in MI (15%; $P = 0.014$) and all-cause mortality (13%; $P = 0.007$) in the intensively treated group versus the conventional group was reported.[73] Early glycemic control may have long-standing benefits to patients over several decades, despite later glycemic control deterioration. This concept is being called metabolic memory or the legacy effect. These studies lay the framework for why early intensive glycemic control is important not only for short term, but also long-term prevention of complications.

ACCORD, ADVANCE, and VADT

The Action to Control Cardiovascular Risk in Diabetes (ACCORD),[74] Action in Diabetes and Vascular Disease (ADVANCE),[75] and Veterans Affairs Diabetes Trial (VADT)[76] were three trials that reported on the effects of glycemic control and macrovascular disease risk.

ACCORD randomized 10,251 high CVD risk subjects (CVD event or significant risk) with type 2 DM to intensive glycemic control (goal HbA_{1c} <6%) or standard glycemic control (HbA_{1c} 7.0%–7.9%). Multiple oral agents and/or insulin were allowed to achieve glycemic goals. Baseline HbA_{1c} level was 8.1%, and the intensive glycemic group achieved a HbA_{1c} of 6.4%, whereas standard glycemic control achieved a HbA_{1c} of 7.5% when the study stopped after a mean follow-up period of 3.5 years. The study was stopped after an interim analysis reported an increase rate of mortality in the intensive arm (1.41 vs 1.14%/year; HR, 1.22; 95% CI, 1.01–1.46). Interestingly, the primary endpoint (myocardial, stroke, or cardiovascular death) was trending down due to a lower risk of nonfatal MI in the intensive therapy group. In addition, on subset analysis, individuals with a baseline HbA_{1c} <8.0% or no previous CVD had a significant reduction in the primary outcome. Increased mortality could not be associated with a specific medication, hypoglycemia (higher in intensive group), lipid levels, or weight gain, though substantially increased in the intensive group. The dichotomous results have been hard to explain, though the ACCORD investigators reported that in the intensive group, it was subjects who could *not* attain intensive glycemic control goals who were at higher risk, not subjects who did achieve the goal. A 20% higher risk of death for each 1% above a HbA_{1c} of 6% was reported.

ADVANCE randomized 11,140 subjects to intensive (≤6.5% HbA_{1c}) or standard therapy (investigator-driven goals). Extended-release gliclizide, a sulfonylurea available outside of the United States, was used as first-line therapy in the intensive group versus no gliclizide in the standard therapy group, though multiple other agents were needed in both groups. A baseline HbA_{1c} was only 7.5%, and at the end of therapy, the intensive group versus standard group HbA_{1c} was ~6.5% versus ~7.2%. ADVANCE reported a significant reduction in renal events, including new or worsening nephropathy (HR, 0.79; 95% CI, 0.66–0.93), but no difference in major macrovascular events (HR, 0.94; 95% CI, 0.84–1.06) with intensive versus standard therapy.

VADT randomized 1,791 subjects to intensive glycemic control (HbA_{1c} goal <6.0%, and action required of >6.5%) versus nonintensive glycemic control (investigator determined). At entry, the HbA_{1c} was the highest of the three trials (9.4%). Multiple medications including insulin were used to achieve glycemic control. The intensive group achieved a HbA_{1c} of 6.9% versus 8.5% in the investigator determined group. The primary endpoint of nonfatal MI, nonfatal stroke, CVD death, hospitalization for heart failure, and revascularization was not significantly different (HR, 0.88; 95% CI, 0.74–1.05) and mortality was unchanged.

These three trials should be viewed as confirmatory that short term (3–5 years) of intensive glycemic control do not positively affect the risk of macrovascular risk in type 2 DM. ACCORD reported that a subset of subjects that could not achieve intensive glycemic control may be at higher risk of death, but identifying these patients and implementing this recommendation into clinical practice may prove to be challenging. As previously mentioned in the EDIC and follow-up of the UKPDS, reduction of macrovascular events from improved glycemic control may take over a decade to come to fruition.

THERAPEUTICS

8 Knowledge of the patient's quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations and other injectables, and pharmacology of oral and antidiabetic agents for type 2 DM are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.

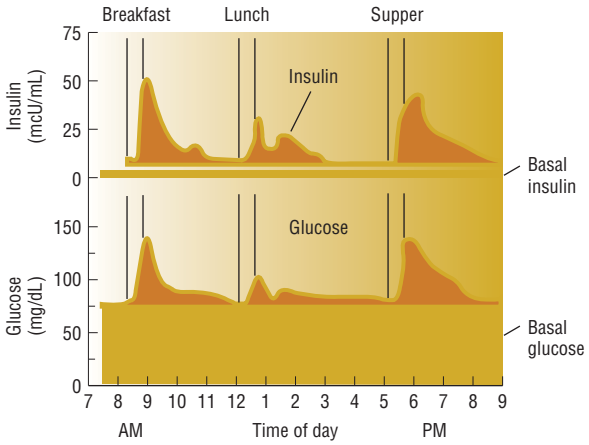
Type 1 Diabetes Mellitus

The choice of therapy for type 1 DM is simple: all patients need insulin. However, how that insulin is delivered to the patient is a matter of considerable practice difference among patients and clinicians. Historically, after the discovery of insulin by Banting and Best in 1921, frequent injections of regular insulin (initially the only insulin available) were given. Modifications of insulin led to longer-acting insulin suspensions and the use by many patients of one or two shots of longer-acting insulin each day. Because self-monitored blood glucose and HbA_{1c} testing were not available at that time, patients and practitioners had no idea how well their patients' blood glucose concentrations were controlled, other than a vague sense from an indirect method, measurement of glucose in the urine. While the renal threshold for glucose is relatively predictable in young healthy subjects, it is highly variable in older patients and patients with renal disease. The advent of SMBG and HbA_{1c} testing in the 1980s revolutionized the care of diabetes, enabling patients and practitioners to directly access blood glucose for assessment, and enabling the patient to make instantaneous changes in the insulin regimen if need be. Modern diabetes management would be impossible without these two tools.

Contemporary management of type 1 DM attempts to match carbohydrate intake with glucose-lowering processes, most commonly insulin, as well as with exercise. Attempts are made to allow the patient to live as normal a life as possible. Understanding the principles of glucose input and glucose egress from the blood will allow the practitioner and the patient great latitude in the management of patients with type 1 DM.

Simplistically speaking, one can break down normal insulin secretion into a relatively constant background level of insulin ("basal") for the fasting and postabsorptive period, and prandial spikes of insulin after eating ("bolus") (Fig. 83–8).[77] Insulin sensitivity and insulin secretion are not constant throughout the day, rendering the basal concept inaccurate. However, in most clinical situations, this approach provides a useful paradigm for understanding and applying insulin treatment for type 1 DM. The other basic principle to consider is that the timing of insulin onset, peak, and duration of effect must match meal patterns and exercise schedules to achieve near-normal blood glucose values throughout the day.

Historically, complexity of insulin regimens has usually been related to the number of injections of insulin administered per



Intensive insulin therapy regimens

	7AM (meal)	11 AM (meal)	5 PM (meal)	Bedtime
1. 2 doses,[a] R or rapid acting + N	R, L, A, GLU + N		R, L, A, GLU + N	
2. 3 doses, R or rapid acting + N	R, L, A, GLU + N	R, L, A, GLU	R, L, A, GLU + N	
3. 4 doses, R or rapid acting + N	R, L, A, GLU	R, L, A, GLU	R, L, A, GLU	N
4. 4 doses R or rapid acting + N	R, L, A, GLU + N	R, L, A, GLU	R, L, A, GLU	N
5. 4 doses,[b] R or rapid acting + long acting	R, L, A, GLU	R, L, A, GLU	R, L, A, GLU	G or D[b] (G may be given anytime every 24 hours)
	← Adjusted basal →			
6. CS-II pump	Bolus	Bolus	Bolus	
7. 3 doses pramlintide added to regimens above	P	P	P	

[a]Many clinicians may not consider this intensive insulin therapy
[b]May be given BID in type 1 DM = 5 doses

FIGURE 83-8. Relationship between insulin and glucose over the course of a day and how various insulin and amylinomimetic regimens could be given. (A, aspart; CS-II, continuous subcutaneous insulin infusion; D, detemir; G, glargine; GLU, glulisine; L, lispro; P, pramlintide; N, NPH; R, regular.)

day. This is a reasonable classification. Clearly one injection of any insulin preparation daily will in no way mimic normal physiology, and therefore is unacceptable. Similarly, two injections of any insulin daily will fail to replicate normal insulin release patterns. Injection regimens that begin to approximate physiologic insulin release start with "split-mixed" injections of a morning dose of an intermediate acting insulin such as neutral protamine Hagedorn (NPH) and a "bolus" rapid-acting insulin or regular insulin before breakfast, and again before the evening meal. The presumption is made that the morning intermediate-acting insulin gives basal insulin for the day and covers the midday meal, the morning bolus insulin covers breakfast, the evening intermediate-acting insulin gives basal insulin for the rest of the day, and the evening bolus insulin covers the evening meal. If patients are very compulsive about consistency of timing of their injections and meals and intake of carbohydrate, such a strategy may be successful. However, most patients are not sufficiently predictable in their schedule and food intake to allow "tight" glucose control with such an approach.

The first modification that is frequently made to such a regimen is the movement of the evening NPH to bedtime (now three total injections per day) because the fasting glucose in the morning is too high. This approach improves glycemic control and reduces hypoglycemia, sufficiently intensifying the insulin therapy for some patients. However, many patients need a more intense approach that also allows greater flexibility in their lifestyle.

9 The basal-bolus concept is an attempt to replicate normal insulin physiology with a combination of intermediate- or long-acting insulin to give the basal component, and rapid-acting insulin to give the bolus component. Various strategies have been used for the former, including once- or twice-daily NPH or detemir, or once-daily insulin glargine. Most type 1 DM patients require two shots of all of the above insulins except insulin glargine. Insulin glargine or insulin detemir is a feasible basal insulin supplement for most patients with type 1 DM. The bolus insulin component is given before meals with regular insulin, insulin lispro, insulin aspart, or insulin glulisine. The rapid onset of action and short time course of rapid-acting insulin analogs more closely replicate normal physiology. This approach allows the patient to vary the amount of insulin injected, depending on the preprandial SMBG level, the anticipated activity (upcoming exercise may reduce insulin requirement), and anticipated carbohydrate intake. Most patients will have a prescribed dose of insulin preprandially that they vary by use of an "adjusted scale insulin" or "correction factor" to normalize a high plasma glucose reading in addition to the amount for the anticipated carbohydrate intake. A starting or empiric "correction factor" can be calculated to provide an approximate plasma glucose lowering (mg/dL) effect of 1 unit of short-acting insulin. Take 1,500 divided by the total daily insulin dose the patient currently uses. For rapid-acting insulins, some experts use 1,700 to 1,800 to account for the rapid reduction in glucose after injection. For example, if a patient is taking 45 units of basal insulin and 10 units of rapid-acting insulin at each of three meals, the total daily insulin dose equals 75 units. 1,500 divided by 75 is 20, thus each unit of insulin will lower the plasma glucose approximately 20 mg/dL. Follow-up SMBG data should be implemented to individualize the correction factor. Carbohydrate counting is a very effective tool for determining the amount of insulin to be injected preprandially. Although general algorithms for carbohydrate counting give rough guidelines, each patient will have to adjust the prescribed preprandial insulin dosage based on their response to different food items. An empiric estimate of how much carbohydrate (grams) 1 unit of rapid-acting insulin will cover is to take 500 divided by the total daily dose of insulin. If we add to the example above with a total daily insulin dose of 75 units, we would take 500 divided by 75, we find that empirically, 1 unit of rapid-acting insulin will cover approximately 7 g of carbohydrate. Follow-up SMBG data should be implemented to individualize this ratio.

In type 1 DM, approximately 50% of insulin replacement should be basal insulin, and the other 50% bolus insulin, split among the meals. If the patient's ratio is not near this recommendation, a reassessment of the regimen should be implemented. Empirically, patients may be begun on ≈0.6 units/kg/ day with basal insulin 50% of total dose and prandial insulin 20% of total dose prebreakfast, 15% prelunch, and 15% presupper. Type 1 DM patients generally require between 0.5 and 1 unit/kg/ day. The need for significantly higher amounts of insulin suggests the presence of insulin antibodies or insulin resistance (coexistent endocrinopathy or type 2 DM).

Obviously, insulin pump therapy (continuous subcutaneous insulin infusion [CSII], generally using a rapid-acting analog insulin) is the most sophisticated form of basal bolus insulin delivery system. CSII may be slightly more efficacious in achieving good glycemic control than multiple-dose insulin injections in a motivated patient. Extensive discussion of this mode of therapy is beyond the scope of this text. Nevertheless, the basic principles for implementation are the same. The one advantage of pump therapy is that the

basal insulin dose may be varied, consistent with changes in insulin requirements throughout the day. In selected patients, this feature will allow greater glycemic control with CSII. However, insulin pumps require even greater attention to detail and frequency of SMBG than four injections daily.[78] In appropriately selected patients willing to pay sufficient attention to detail of SMBG and insulin administration, CSII can be a very useful form of therapy. CSII is a tool for diabetes control, and if the patient is not well controlled or unwilling to actively control the diabetes on injections, it is unlikely that the patient will have superior control on a pump.

Intensive therapy (basal bolus) to all adult patients with type 1 DM at the time of diagnosis is recommended to reinforce the importance of glycemic control from the outset rather than change strategies over time after lack of control. Occasional patients with an extended honeymoon period may need less intense therapy initially, but should be converted to basal bolus therapy at the onset of glycemic lability. For patients insisting on two injections daily, intermediate-acting insulin and a rapid-acting insulin or regular insulin (starting at 0.6 units/kg with two-thirds in the morning, two-thirds of the morning dose as intermediate acting insulin, and one-half of evening dose as intermediate-acting insulin) may be sufficient. Regardless of the regimen chosen, gross adjustments in the total insulin dose can be made based on HbA_{1c} measurements and symptoms such as polyuria, polydipsia, and weight gain or loss. Finer insulin adjustments can be determined on the basis of the results of frequent SMBG.

All patients receiving insulin should have extensive education in the recognition and treatment of hypoglycemia. Questioning about the recognition of hypoglycemia is warranted at each patient visit. Documentation of frequency of hypoglycemia, particularly that requiring assistance of another person, visit to an emergent or urgent care facility, or hospitalization, should be recorded. In type 1 DM, the development of hypoglycemia unawareness is common. It may result from progression of disease with autonomic neuropathy. Loss of adrenergic warning signs in such a situation is a relative contraindication to intensive insulin therapy. More commonly, type 1 DM patients have loss of warning signs because of a presumed lower set point for release of counterregulatory hormones as a result of frequent episodes of hypoglycemia ("hypoglycemia begets hypoglycemia"). In such situations, more normal hypoglycemia awareness may be restored by reduction or redistribution of the insulin dose to eliminate significant hypoglycemic episodes. Short-term treatment with theophylline will improve hypoglycemia awareness.[79] Other interventions that may help include coffee consumption or sympathomimetics. These therapies, other than possibly coffee, should not routinely be employed, but may be considered in refractory cases.

Children and pubescent adolescents, glycemic goals should be tempered with the risks of hypoglycemia. Table 83–7 lists glycemic goals for different age groups of type 1 DM patients. Therefore it is not unreasonable to use less intense management (two shots per day, premixed insulins) until the patient is postpubertal, if age specific goals can be maintained.[80]

Occasional patients have antibodies to injected insulin, but the significance of the antibodies is usually minimal. Human insulin therapy has not totally eliminated insulin allergies, although most patients have a local reaction that will dissipate over time. If mild reactions at the site of injection occur, assess the insulin injected. Many times the patient injects cold insulin, which causes vasodilation around the injection site. Anecdotally, a different source could be tried as well (yeast based if on *E coli* based, and vice versa). If the allergic reaction does not improve or is systemic, insulin desensitization can be carried out.[81] Protocols for desensitization are available from major insulin manufacturers. While more common in the animal insulin era, lipohypertrophy is still seen in some patients with long-standing type 1 DM. Such patients give their insulin injections in the same site to minimize discomfort. Because insulin absorption from an area of lipohypertrophy is unpredictable, avoidance of injections into these areas is mandatory.

Several common errors can occur in the therapy of patients with type 1 DM, causing erratic glucose fluctuations:

- Failure to take into account peaks of insulin action when using a peaking insulin and planning meals and/or activity. Eating should be planned around the peaks of the insulin.
- Random rotation of insulin injection sites. There is sufficient variability of insulin absorption from site to site that this practice alone may cause wide glucose swings. The most consistent absorption of insulin is from the abdominal wall. We try to get our patients to take all their injections in the abdomen. If the patient is unable or unwilling to follow this advice, then systematic site rotation is the next preferable option. The patient always gives the insulin injection in the same region of the body the same time of the day each day. For instance, the arms are always used every morning. Needless to say, the patient should not inject in a limb and then go out and exercise that limb, increasing blood flow and insulin absorption.
- Overinsulinization is a very common problem. The answer to all high blood glucose is not necessarily more insulin, as the patient may be insulinopenic, or may be "rebounding" from a previous low glucose and treating it with excessive amounts of carbohydrate. Fastidious SMBG, particularly during the night (or selected use of continuous glucose monitoring) will help sort this out. Also, practitioners sometimes do not adequately differentiate type 1 DM from type 2 DM when using insulin. Patients with type 1 DM are insulinopenic but have normal insulin sensitivity. Patients with type 2 DM have varying degrees of insulin resistance. Therefore, a 1 unit change in the dose of insulin for a patient with type 1 DM may have a dramatic effect on glucose concentrations, whereas in some patients with type 2 DM 10 to 20 times that amount of insulin may have little effect on glucose. Large changes in insulin dose in patients with type 1 DM are not usually indicated unless the patient's blood glucose control is very poor. Widely erratic SMBG results and/or weight gain often suggest overinsulinization.
- When in doubt, always double check the patient's technique for insulin dosing, insulin injection, and SMBG. Sometimes the simplest of errors results in miserable glycemic control.

Pramlintide in type 1 DM patients who continue to have erratic postprandial control despite implementation of the above strategies may be appropriate. It is imperative at initiation of therapy with pramlintide that each dose of prandial insulin (rapid-acting analog or regular insulin) be reduced by 30% to 50%, or severe hypoglycemic reactions may occur. Pramlintide should be judiciously titrated based on gastrointestinal adverse effects and postprandial glycemic goals. Anecdotally, due to delayed gastric emptying, injecting pramlintide prior to the meal and the rapid acting insulin after the meal may better match the appearance of the food with the postprandial increase in glucose. As pramlintide is not recommended for mixing, you are adding an additional prandial injection at each meal. A patient that is cognizant of the hypoglycemic risk, gastrointestinal side effects, and effective strategies to reduce both issues is needed.

Islet cell and whole pancreas transplantation are occasionally used in patients who require immunosuppressive therapy for other reasons, such as renal transplants.[82] There has been considerable interest in islet cell transplantation since investigators in Edmonton reported success without using glucocorticoids as

immunosuppressive agents.[83] Some of these patients are able to stop insulin, though many require insulin secretion support from sulfonlyureas or GLP-1 agonists.

Type 2 Diabetes Mellitus

Pharmacotherapy for type 2 DM has changed dramatically in the last few years with the addition of several new drug classes and recommendations to achieve more stringent glycemic control. Symptomatic patients may initially require treatment with insulin or combination oral therapy to reduce glucose toxicity (which may reduce β-cell insulin secretion and worsen insulin resistance). Patients with HbA_{1c} ≈7% or less are usually treated with therapeutic lifestyle measures and an agent which will not cause hypoglycemia. Those with HbA_{1c} >7% but <8.5% could be initially treated with single oral agents, or low dose combinations. Patients with higher initial HbA_{1c} may benefit from initial therapy with two oral agents, or even insulin.

⑩ Depending on patient motivation and adherence to therapeutic lifestyle changes, most patients with HbA_{1c} greater than 9% to 10% will likely require therapy with two or more oral agents to reach glycemic goals. Treatment of type 2 DM often necessitates use of multiple therapeutic agents (combination therapy), to obtain glycemic goals.

The best initial oral therapy for patients with type 2 DM is widely debated. Based on the results of the UKPDS and safety record, obese patients (>120% ideal body weight) without contraindications should be started on metformin titrated to ≈2,000 mg/day.[84] Near-normal weight patients may be better treated with insulin secretagogues, though metformin will work in this population. Metformin is the only oral antihyperglycemic agent to ever report a reduction in total mortality. Despite this, long-term durability of HbA_{1c} reduction, due to the inability to stop progressive β-cell failure, is suboptimal with metformin, and patients over several years will often need additional therapy. An insulin secretagogue, such as a sulfonylurea, is often added second, though it has clearly been shown that sulfonylureas do not produce durable HbA_{1c} reductions. Better choices to sustain HbA_{1c} reductions would be a TZD or GLP-1 agonist. Goal-oriented therapy is what we should strive for, meaning the intervention should be in relation to the distance from the goal. When initial therapy is no longer keeping the patient at goal, if the HbA_{1c} is close to goal, one additional agent may be appropriate. If >1% to 1.5% above goal, it is unlikely any one oral agent will result in reaching the glycemic goal, and multiple oral agents or insulin therapy may be appropriate. Thiazolidinediones may be substituted in situations in which a patient is intolerant of, or has a contraindication to, metformin as an insulin sensitizer, understanding that thiazolidinediones should be used with caution in heart failure. Figure 83–9 is an algorithm developed by the Texas Diabetes Council for glycemic control. No algorithm can substitute for good clinical judgement, and algorithms for glycemic control start with the premise that the clinician will identify medication contraindications, adverse reactions, and comobidities that may be advantageous or harmful if the medication was taken.

We should also treat type 2 DM by matching therapy to the suspected underlying problem. Consider some simple questions to guide therapy: (1) How long has the patient had diabetes? The longer a patient has had diabetes, the more insulinopenic they likely are and the more likely that insulin therapy will be needed; (2) Fasting, postprandial, or both plasma glucose issue? Some drugs address postprandial better, whereas some address FPG better; (3) How far do we have to go to goal and what is the goal? Each oral agent has limits on HbA_{1c} reduction, and the reduction is baseline HbA_{1c} dependent; (4)Adverse effect profile? Contraindications, hypoglycemia potential, and tolerability are based on the current status of the patient; (5) Comorbidities? CVD, dementia, life expectancy, depression, osteoporosis, and other conditions where select medications may be poor choices and additionally those comorbidities may drive our HbA_{1c} goal. Based on the ADVANCE, ACCORD, and VADT trials, a HbA_{1c} goal may now be above 7% if certain comorbidities are present. See Figure 83–10 for HbA_{1c} individualization based on comorbidities from the Texas Diabetes Council. Drugs such as metformin, TZDs, sulfonylureas, repaglinide, liraglutide, intermediate-acting insulins given at bedtime, and basal insulins control fasting plasma glucose more effectively. Exenatide, DPP-4 inhibitors, α-glucosidase inhibitors, nateglinide, and regular and rapid acting insulin better control postprandial glucose excursions. We can also guide therapy based on the risk of hypoglycemia. Metformin, TZDs, liraglutide, exenatide, DPP-4 inhibitors and α-glucosidase inhibitors have a low risk of hypoglycemia. Combining these agents will allow aggressive targeting of near-normal HbA_{1c} levels while minimizing hypoglycemia and weight gain. Combining these agents early in the diagnosis of type 2 DM is logical to potentially realize the micro- and macrovascular reduction seen in the long-term follow-up of UKPDS.

Preserving β-cell function, thus arresting the progressive nature of type 2 DM, could be paradigm changing, but to date medications have only shown to slow, not arrest progression. In the UKPDS, insulin, metformin, or sulfonylureas did not halt β-cell failure. Thiazolidinediones and GLP-1 agonists (open label exenatide has shown durable HbA_{1c} reduction to 3 years and liraglutide to 2 years) may potentially slow β-cell failure.[85,86] It appears unlikely any one drug class will arrest β-cell failure. Combination therapy with TZDs and GLP-1 agonists is logical as TZDs reduce apoptosis of β cells and GLP-1 agonists augment pancreatic function through insulin secretion in a glucose dependent manner and reduction of inappropriate glucagon, but long-term data is lacking. β-cell function is heavily damaged by the time type 2 DM is diagnosed, and it is possible that β-cell failure is inevitable by type 2 DM diagnosis. HbA_{1c} reduction is dependent on baseline values, with higher reductions seen with higher values, but again, therapy should be goal oriented. Triple therapy is often with metformin, a sulfonylurea, and a TZD or DPP-4 inhibitor, but, a good alternative is to use metformin, a TZD, and a GLP-1 agonist, which can lower glucose levels and increase satiety, reducing the weight gain potential of a TZD, and still has a low risk of hypoglycemia. If the HbA_{1c} is >8.5% to 9% on multiple therapies, insulin therapy should be considered. Sulfonylureas are often stopped when insulin is added and insulin sensitizers continued. This may be beneficial to decrease hypoglycemia, but continuing the sulfonylurea is permissible until multiple daily injections are started, at which time it should definitely be discontinued.

Virtually all patients with type 2 DM ultimately become relatively insulinopenic and will require insulin therapy. Insulin therapy for type 2 DM has changed dramatically in the last few years. Specifically, patients are often "transitioned" to insulin by using a bedtime injection of an intermediate- or long-acting insulin, and using oral agents primarily for control during the day.[87,88]

This strategy leads to less hyperinsulinemia during the day and is associated with less weight gain and has equal efficacy and a lower risk of hypoglycemia for up to 3 years when compared to starting prandial insulin or split-mix twice daily insulin.[89] Because most patients are insulin resistant, insulin sensitizers are commonly used with insulin therapy. Patients with type 2 DM are usually well buffered against hypoglycemia. Patients should be monitored for hypoglycemia by asking about nocturnal sweating, nightmares (both indicative of nocturnal hypoglycemia), palpitations, tremulousness, and neuroglycopenic symptoms, as well as SMBG. When bedtime insulin plus daytime oral medications fail to achieve glycemic goals, a conventional multiple daily dose insulin regimen while continuing the insulin sensitizers is often tried. This may mean adding an injection of bolus insulin with

the largest meal of the day for a total of two injections. If this is unsuccessful, a bolus injection can be given with the second largest meal of the day, for a total of three injections. After this, the standard basal-bolus model is followed. Alternatively, patients may be switched to split mix insulin such as 70/30 mix insulin, Humalog Mix 75/25 or Novolog Mix 70/30. These are often given twice daily before the first and third meal (see type 1 DM for longer explanation) but if inadequate control is seen, a third dose of mix insulin may be given with the third meal of the day. This allows for better mealtime coverage, but can also increase the risk of hypoglycemia. Use of exenatide or pramlintide for prandial coverage can be considered. Exenatide should be injected twice daily before meals, whereas pramlintide can be given before each meal. Concerns and problems with insulin administration as addressed in the section on type 1 DM generally relate to the therapy of type 2 DM. However, patients with type 2 DM rarely have hypoglycemia unawareness. Also, the variability of insulin resistance means that insulin doses may range from 0.7 to 2.5 units/kg or more. Figure 83–11 is an algorithm for insulin therapy options in type 2 diabetes developed by the Texas Diabetes Council. This algorithm gives most options for insulin therapy, but the choice of regimen should be individualized based on the discussion with the patient.

The availability of short-acting insulin secretagogues, rapid-acting insulin analogs, exenatide, DPP-4 inhibitors, and α-glucosidase inhibitors, all of which target postprandial glycemia, has reminded practitioners that glycemic control is a function of fasting and preprandial glycemia and postprandial glycemic excursions.[90] Therefore, postprandial glucose measurements may need more emphasis if the HbA_{1c} is near the glycemic goal. Currently, it remains controversial whether targeting after-meal glucose excursions will have more of an effect on complications risk than

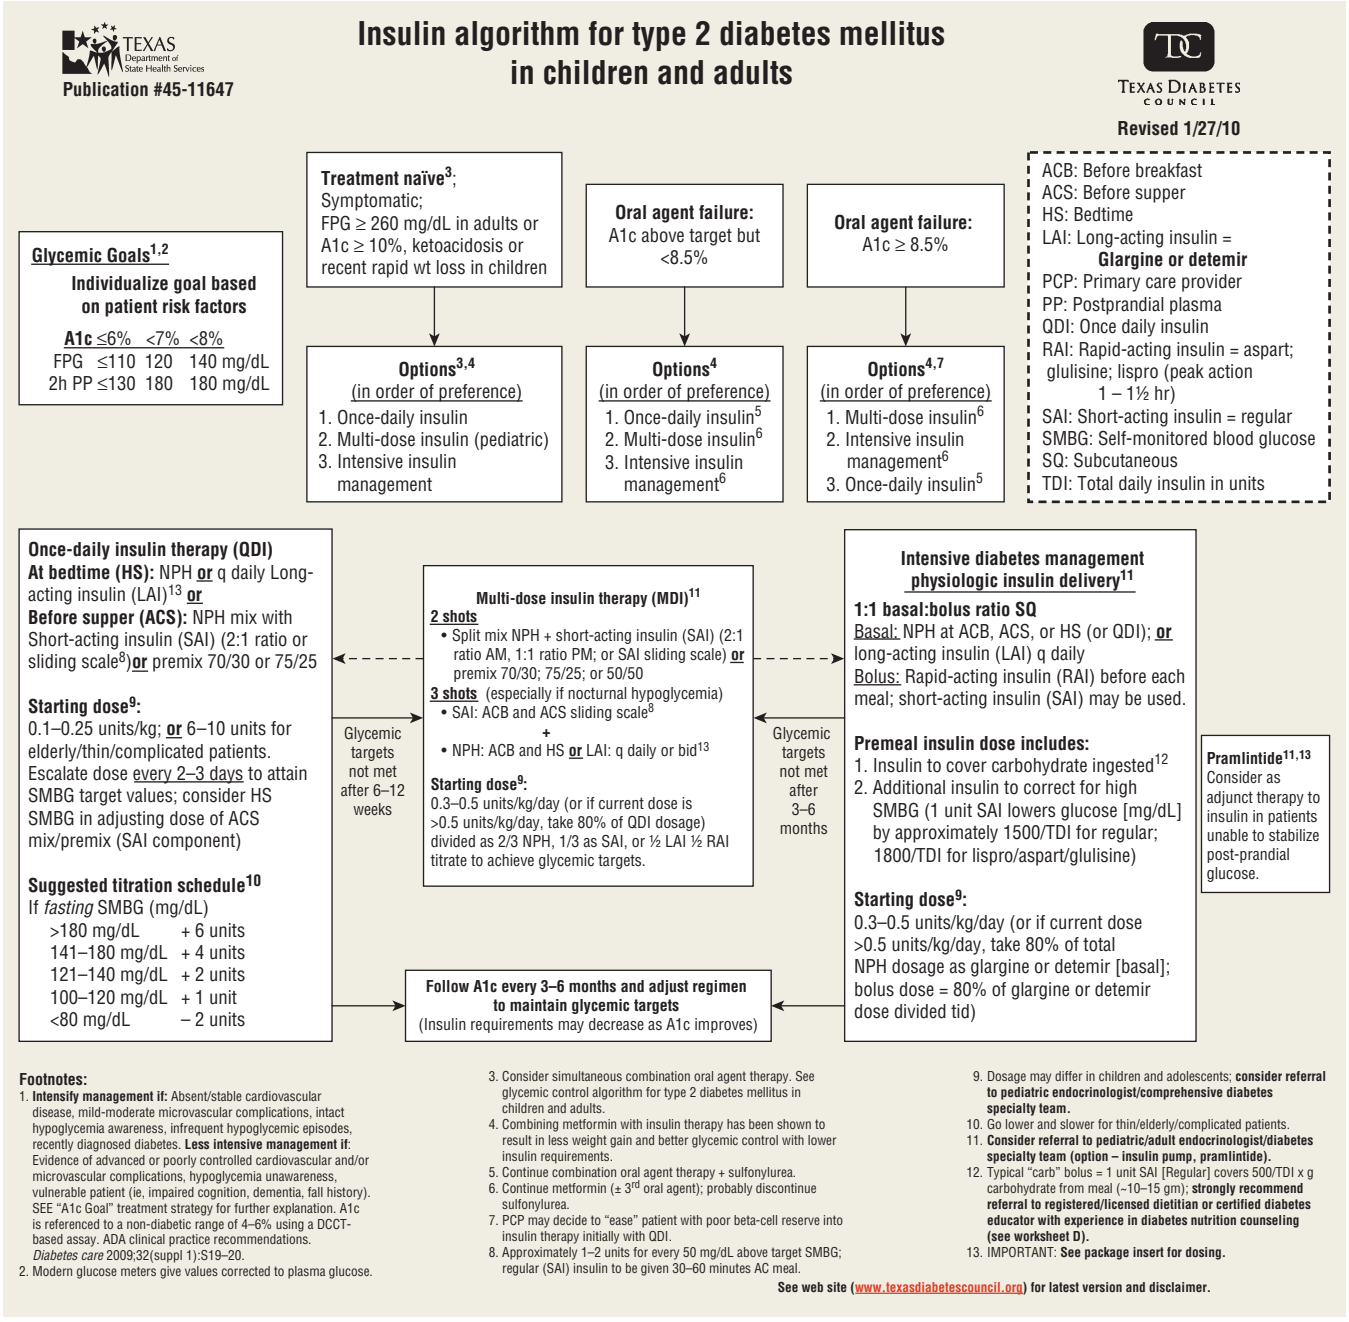

FIGURE 83-11. Insulin algorithm for type 2 DM in children and adults. See *www.texasdiabetescouncil.org* for current algorithms. *(Reprinted with permission from the Texas Diabetes Council.)*

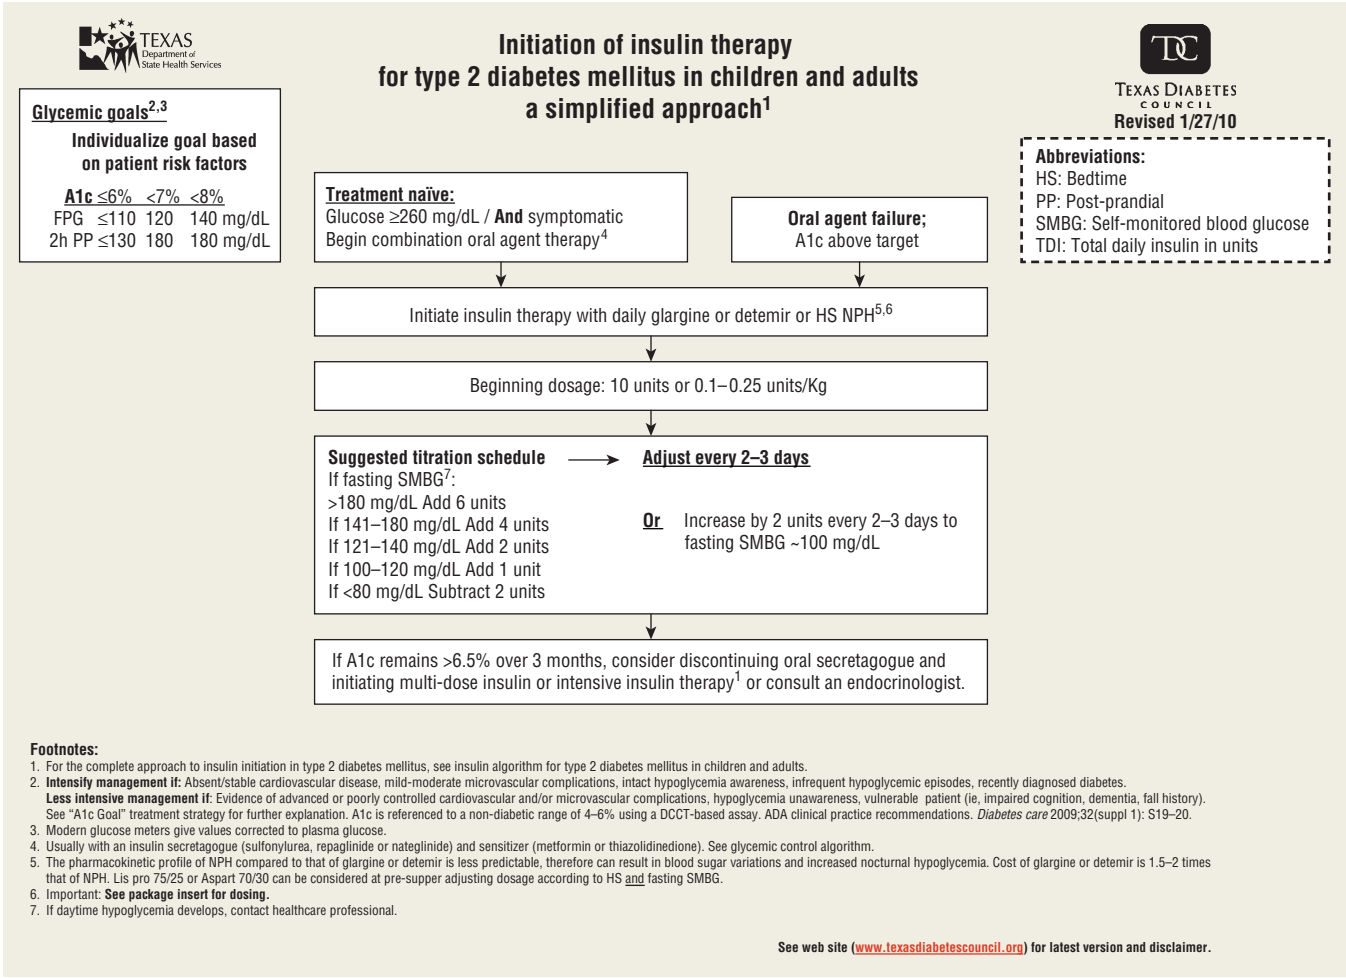

FIGURE 83-11. *(continued)*

more conventional strategies. Importantly, postprandial excursions proportionally contribute more than the FPG to the HbA_{1c} percentage when the HbA_{1c} nears goals, and thus will need to be targeted for optimal glycemic control in many patients. Most evidence is mostly in epidemiologic studies with post-glucose challenge glucose measurements in diabetes and nondiabetes subjects, not in prospective studies.[91]

SPECIAL POPULATIONS

Children and Adolescents with Type 2 DM

Type 2 DM is increasing in adolescence.[10] Obesity and physical inactivity seem to be particular culprits in the pathogenesis of this disease. Given the many years that the patient will have to live with diabetes, and recent evidence that the timeline for complications may mimic that of older adults, extraordinary efforts should be expended on lifestyle modification measures in an attempt to normalize glucose levels. Failing that strategy, the only labeled oral agent for use in children (10–16 years of age) is metformin, though sulfonylureas are also commonly used in therapy. Thiazolidinediones have not been studied in children, but studies to ascertain safety and efficacy are currently under way. Exenatide, as it potentially helps the child to lose weight, is also increasing, but the long-term effects of this therapeutic modality are unknown. Exenatide has been submitted to the FDA for approval in children. In adolescent females, the possibility of future pregnancy should be considered in the prescription of any drug regimen.

Elderly Patients with DM

Elderly patients with newly diagnosed DM (almost always type 2 DM) present a different therapeutic challenge. Consideration of the risks of hypoglycemia in this population and the probable life span should help determine if less stringent glycemic goals should be set. Thinner, older patients may primarily be treated with shorter-acting insulin secretagogues, low-dose sulfonylureas (preferably not long-acting ones), DPP-4 inhibitors, or α-glucosidase inhibitors. The risk for lactic acidosis, which increases with older age and the age-related decline in renal function, makes metformin therapy more problematic. In a patient whom weight gain or loss may not be unwelcome, thiazolidinediones or exenatide, respectively, may be considered, but falls risk and fracture risk must be considered with TZDs. DPP-4 inhibitors or α-glucosidase inhibitors may be advantageous due to low risk of hypoglycemia. Simple insulin regimens such as an injection of basal insulin daily may be appropriate for glycemic control in elderly patients with newly diagnosed DM.

Gestational DM and Pregnancy with Preexisting Diabetes

Gestational DM is diagnosed as previously described. Dietary therapy to minimize wide fluctuations in blood glucose is of paramount importance.[8,12] Intensive educational efforts are usually necessary. Pregnant women without DM maintain plasma glucose concentrations between 50 and 130 mg/dL. Frequent SMBG is needed to tell whether dietary interventions are successful. If

Worksheet

Advancing to intensive/physiologic basal: bolus insulin therapy

TEXAS DIABETES COUNCIL

Revised 1/27/10

Note: "Analog" = Rapid acting (bolus) analog insulin throughout this document.

A. Conversion from once-daily insulin to intensive/physiologic insulin replacement:

Oral therapy failure: once-daily glargine was added to the oral regimen and titrated to 30 units per day. How do you add analog insulin if the patient reports the following SMBG values?

	FPG	2-hr pp Brkfst	2-hr pp Lunch	2-hr pp Dinner
Case 1	105	140	140	240
Case 2	105	140	190	240
Case 3	105	190	240	240

Case 1

a. Continue the oral agents (± sulfonylurea) and 30 units glargine or detemir (or NPH)
b. There are 2 approaches for adding analog (RAI) 10–15 minutes before a meal:

#1	Arbitrary start: Titrate:	5 units Add 2 units every 2 days to reach 2-hr pp goal
#2	Carb-counting Titrate:	1 unit/50 mg/dL over 2-hr pp goal *Plus* 1 unit/15 grams carbohydrate Add 1 unit/50 mg/dL >2-hr pp goal every 2 days

Cases 2 and 3

As above, but add and titrate analog before each meal where the postprandial glucose is above goal. Also, see part D, below for more information on how to optimize the use of analog insulin. Re-evaluate each week to be certain that about half of the total daily dose is basal and half is bolus insulin.

B. Conversion from once-daily premix to intensive/physiologic insulin replacement:

Oral therapy failure: once-daily 70/30 premixed insulin was added and titrated to 30 units per day. The fasting glucose is at goal, but daytime control is poor. How do you convert to physiologic insulin therapy?

a. **Basal insulin dose:** The first step in the conversion is based on the total dose of intermediate-acting insulin. In this case, the person is taking 21 units of NPH or aspart-protamine insulin (70% x 30 units = 21 units). So, give 21 units basal glargine (use "unit-for-unit" conversion for once-daily intermediate regimens.) *Remember, do not stop oral agents (+ sulfonylurea) at this time.*

b. **Bolus insulin dose:** There are several ways to start the analog.
i. *See Case 1, page 2 (Arbitrary start or Carb-counting)*
ii. Begin with the previous dose of fast-acting insulin, divide it before meals and titrate every 2 days. In this case, the person was using 30 units of 70/30 or about 9 units of fast-acting insulin (30% x 30 units = 9 units). So give 3 units of analog before each meal and titrate every 2 days as per Case 1.

FIGURE 83-11. *(continued)*

fasting plasma glucose is >105 mg/dL, or 1-hour postprandial plasma glucose levels are >155 mg/dL, or if 2-hour postprandial plasma glucose levels are >130 mg/dL, insulin therapy is usually begun, but more aggressive use of medication is sometimes used by some clinicians. Goals during therapy are a preprandial goal of ≤95 mg/dL, and either a 1-hour postprandial plasma glucose levels ≤140 mg/dL, or 2-hour postprandial plasma glucose levels ≤120 mg/dL, and avoidance of ketones as much as possible. In patients who have preexisting type 1 or type 2 diabetes and become pregnant, premeal, bedtime, and overnight glucose should be 60 to 99mg/dL, with a peak postprandial of 100 to 129mg/dL. HbA_{1c} during pregnancy should be less than 6%. Titration of insulin and switching to more complicated regimens is guided by SMBG results. Use of basal insulins other than NPH is still debated, but with the ease of use of detemir or glargine insulin, their use in gestational DM will likely increase. In addition, pump therapy for the duration of the pregnancy is often instituted, as it can obtain excellent glycemic control and is quickly adjustable. Despite the long-standing labeling of sulfonylureas as contraindicated in pregnancy, one randomized, open-label, controlled trial evaluated the efficacy of glyburide as compared to insulin initiated after 11 weeks' gestation.[92] Adequate control of blood glucose was achieved as compared to traditional insulin therapy, with less hypoglycemia in the glyburide group. No evidence of any difference in complications, specifically cord-serum insulin concentrations, incidence of macrosomia (birth weight ≥4,000 g), cesarean delivery, or neonatal hypoglycemia between regimens were noted. Glyburide was not detected in the cord serum of any infant. As the study limited enrollment beyond 11 weeks' gestation, no conclusions regarding teratogenicity can be made from this study. The ADA cites this study in a position paper and mentions its utility, but also warns that it is not a labeled use of the drug and suggests further studies are needed to establish its safety.[12] In addition, metformin has been studied in the treatment of GDM. Metformin crosses the placenta, but did not increase any complications associated with GDM when compared with insulin therapy, and patients

TEXAS DIABETES COUNCIL
Revised 1/27/10

C. Conversion from twice-daily premix to intensive/physiologic insulin replacement:

Oral therapy failure in an 80 kg person: 70/30 premixed insulin was started and advanced to 60 units per day: 40 units before breakfast and 20 units before dinner. The fasting glucose was at goal, but wide glycemic excursions occurred at other times during the day and night. How do you convert this person to physiologic insulin therapy? There are several approaches. Use which ever method you want.

a. Start over and begin insulin at 0.5 units/kg. Give half as basal insulin and half as analog, divided before meals. In this case, the starting dose would be 40 units per day. Start giving 20 units glargine each morning and about 7 units analog before each meal. Titrate the basal and bolus insulins every 2 days to fasting and 2-hr postprandial goals.

b. Conversion based on current insulin usage:

Basal dose: The first step in the conversion is based on the 80% of the total dose of intermediate-acting insulin. In this case, the person is taking 42 units of NPH or aspart-protamine insulin (70% x 60 units = 42 units). When a person is taking multiple doses of intermediate-acting insulin, we give only 80% as glargine. So, give 34 units basal glargine (80% x 42 = ~34). Remember, *do not stop oral agents (+ sulfonylurea) at this time*.

Bolus insulin dose: There are several ways to start the analog.
i. *See Case 1, page 3 (Arbitrary start or Carb-counting)*
ii. Begin with the previous dose of fast-acting insulin, divide it before meals and titrate every 2 days. In this case, the person was using 60 units of 70/30 or 18 units of fast-acting insulin (30% x 60 units = 18 units). So, give 6 units of analog before each meal and titrate every 2 days as per Case 1.

c. **The "80%-80%"rule":** Similar to the above method, but yields an ideal ratio of basal:bolus insulin in one step. The dose of basal glargine will be 80% of the total intermediate insulin, and the analog will be 80% of the glargine dose, divided before meals.

Basal dose: = 80% of total intermediate insulin
= 80% x 42 units (70% x 60 = 42)
= 34 units glargine
Analog dose: = 80% of the glargine dose, divided TID
= 80% x 34 units = 27 units
= 27 units, divided tid = 9 units
= 9 units aspart, glulisine or lispro before meals

Note: Total dose of insulin is conserved and an ideal ratio between basal and bolus will always result with the "80%–80%" method.

TEXAS DIABETES COUNCIL
Revised 1/27/10

D. Optimizing analog insulin use

Tight control of blood glucose requires that the patient participates in the management of their diabetes. This includes monitoring their blood glucose and learning to count carbohydrates or "carb count." The following material explains how to calculate the dose of analog required to cover a meal and how to add extra analog to correct a hyperglycemic event.

a. Determining the dose of analog insulin to use before a meal

The "Rule of 500" is used to determine how many grams of carbohydrate 1 unit of analog insulin will cover. When this number is known, then the person can easily give the correct dose of analog by simply counting the grams of carbohydrate they intend to eat at the meal.

Specifically, 500 divided by the total daily insulin dose (500/TDI) yields the number of grams of carbohydrate that 1 unit of analog will cover. For example, if a person has established that they require about 50 units of insulin per day, then it follows that 1 unit of analog will cover 10 grams of carbohydrate (500/50 = 10). If the person carb counts 140 grams in the dinner meal, then the dose of analog will be 14 units given 10 minutes before eating.

b. Correcting for hyperglycemia

The "Rule of 1800" is used to determine how much insulin to use to bring a high glucose reading back to goal. Even with tight control, hyperglycemia occurs and people need to be able to correct this situation.

Specifically, 1800 divided by the total daily insulin dose yields a value indicating how much 1 unit of analog insulin will lower the blood glucose. Thus, if a person uses 90 units of insulin per day, then 1 unit of analog will reduce the blood glucose by 20 mg/dL (1800/90 = 20). *This augment dose of insulin can be used by itself to correct hyperglycemia, or added to the bolus dose if glucose is high before a meal.*

FIGURE 83-11. *(continued)*

preferred it overwhelmingly to insulin therapy. Further study is needed prior to recommending metformin in GDM. Patients with gestational DM should be evaluated 6 weeks after delivery to ensure that normal glucose tolerance has returned. Because these patients' long-term risk for the development of type 2 DM is considerable, periodic assessment after that is warranted.

SPECIAL SITUATIONS

Sick Days

Acute self-limited illness rarely presents a major problem for patients with type 2 DM, but can be a significant challenge for insulinopenic type 1 DM patients.[93] While caloric intake generally declines, insulin sensitivity also decreases, meaning that it may take greater amounts of insulin to control blood glucose concentrations. Patients need to be adept at frequent SMBG, checking urine ketones, use of short-acting insulin, and understanding that sugar intake in this situation is not "bad" but may be necessary to balance the glucose levels when extra insulin is needed during illness. We encourage patients to continue their usual insulin regimen and to use supplemental rapid-acting insulin based on SMBG results, with further additional insulin given if ketonuria develops. Sugar and electrolyte solutions, such as sports drinks, can be used to maintain hydration, to provide needed electrolytes if there are significant gastrointestinal or urinary losses, and to provide sugar to keep the patient from developing hypoglycemia because of the extra insulin that is usually needed. In contrast, type 2 patients may need to switch to sugar-free drinks if blood glucose levels are continually elevated. Most patients can be taught how to sufficiently manage sick days and avoid hospitalization.

Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Diabetic ketoacidosis and hyperosmolar hyperglycemic state are true diabetic emergencies.[94] A comprehensive discussion of their treatment is beyond the scope of this chapter. In patients with known diabetes, diabetic ketoacidosis is usually precipitated by insulin omission in type 1 DM, and intercurrent illness, particularly infection, in both type 1 and type 2 DM. However, patients with type 1 or type 2 DM (the latter being usually non-whites or Hispanics) may present at initial presentation. It is possible that some of the patients deemed to have type 2 DM actually have type 1 idiopathic DM. Patients with diabetic ketoacidosis may be alert, stuporous, or comatose at presentation. The hallmark diagnostic laboratory values include hyperglycemia, anion gap acidosis, and large ketonemia or ketonuria. Afflicted patients have fluid deficits of several liters and sodium and potassium deficits of several hundred milliequivalents. Restoration of intravascular volume acutely with normal saline, followed by hypotonic saline to replace free water, potassium supplements, and constant infusion insulin restore the patient's metabolic status relatively quickly. A flow sheet is often helpful in tracking the fluid and insulin therapies and laboratory parameters in these patients. Bicarbonate administration is generally not needed and may be harmful, especially in children. Treatment of the inciting medical condition is also vital. Hourly bedside monitoring of glucose and frequent monitoring (every 2–4 hours) of potassium is essential. Metabolic improvement is manifested by an increase in the serum bicarbonate or pH. Serum phosphorus usually starts high and plummets to lower-than-normal levels, though replacing phosphorus, while not unreasonable, is of questionable benefit in most patients. Fluid administration alone will reduce the glucose concentration, so a decrement in glucose values does not necessarily mean that the patient's metabolic status is improving. Rare patients will require larger amounts of insulin than those usually given (5–10 units/h). We double the patient's insulin dose if the serum bicarbonate has not improved after the first 4 hours of insulin therapy. Constant infusion of a fixed dose of insulin and the administration of intravenous glucose when the blood glucose level decreases to <250 mg/dL is preferable to titration of the insulin infusion based on the glucose level. The latter strategy may delay clearance of the ketosis and prolong treatment. The insulin infusion should be continued until the urine ketones clear and the anion gap closes. Long-acting insulin should be given 1 to 3 hours prior to discontinuing the insulin infusion. Intramuscular regular insulin or subcutaneous insulin lispro or aspart given every 1 to 2 hours can be utilized rather than an insulin infusion in patients without hypoperfusion. Patients may develop hyperchloremic metabolic acidosis with treatment if they have been given large volumes of normal saline in the course of their treatment. Such a situation does not require any specific treatment.

Hyperosmolar hyperglycemic state usually occurs in older patients with type 2 DM, at times undiagnosed, or in younger patients with prolonged hyperglycemia and dehydration or significant renal insufficiency. Large ketonemia is usually not seen, as residual insulin secretion suppresses the production of ketones. Infection or another medical illness is the usual precipitant. Fluid deficits are usually greater and blood glucose concentrations higher (at times >1,000 mg/dL) in these patients than in patients with diabetic ketoacidosis. Blood glucose levels should be lowered very gradually with hypotonic fluids and low-dose insulin infusions (1–2 units/h). Rapid correction of the glucose levels, a drop greater than 75 to 100 mg/dL/h, is not recommended, as it can result in cerebral edema. This is especially true for children with diabetic ketoacidosis. Mortality is high with the hyperosmolar hyperglycemic state.

Hospitalization for Intercurrent Medical Illness

Patients on oral agents may need transient therapy with insulin to achieve adequate glycemic control. In patients requiring insulin, patients should receive scheduled doses of insulin with additional short-acting insulin. "Sliding-scale" insulin is to be discouraged, as it is notorious for not controlling glucose and for sometimes resulting in therapeutic misadventures, with wide swings in the blood glucose as the patient "bounces" from hypoglycemia to hyperglycemia.[95] In-hospital mortality is increased in many hyperglycemic conditions. At least one study documented a reduction in mortality in type 2 diabetes patients with acute MIs[96] who receive constant intravenous insulin during the acute phase of the event to maintain near-normal glucose concentrations. Similar mortality results have been documented in some intensive care unit settings using intravenous insulin and tight glucose control.[96,97] The American Diabetes Association and American Association of Clinical Endocrinologists released a jount consensus statement on inpatient glycemic control stating that glucose control measures should be implemented if the blood glucose is ≥180 mg/dL, and maintained between 140 and 180 mg/dL.[98] The Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation trial, and several other negative trials, have resulted in this loosening of inpatient glycemic goals. Critically ill patients had a higher 90-day mortality when a goal of 81 to 108 mg/dL was targeted than when a blood glucose of ≤180 mg/dL (achieved 144 mg/dL) was targeted.[99] Many protocols for IV insulin infusion are currently available, and implementation for an inpatient setting should use a well-established protocol. It is prudent to stop metformin in all patients who arrive in acute care settings until full elucidation of the reason for presentation can be ascertained, as contraindications to metformin are prevalent in hospitalized patients.

Perioperative Management

Surgical patients may experience worsening of glycemia for reasons similar to those listed above for intercurrent medical illness.[100] Patients on oral agents may need transient therapy with insulin to control blood glucose. In patients requiring insulin, scheduled doses of insulin or continuous insulin infusions are preferred. For patients who can eat soon after surgery, the time-honored approach of giving one-half of the usual morning NPH insulin dose with dextrose 5% in water intravenously is acceptable, with resumption of scheduled insulin, perhaps at reduced doses, within the first day. For patients requiring more prolonged periods without oral nutrition and for major surgery, such as coronary artery bypass grafting and major abdominal surgery, constant infusion intravenous insulin is preferred. Use of intravenous insulin infusion has been shown to reduce deep sternal wound infections in patients after coronary artery bypass grafting, though there is no need to start the infusion during or before the procedure. Metformin should be discontinued temporarily after any major surgery until it is clear that the patient is hemodynamically stable and normal renal function is documented.

Reproductive-Age Women and Preconception Care for Women

An increasing prevalence of DM has been noted in reproductive-age women.[101,102] Prepregnancy planning is absolutely mandatory, as organogenesis is largely completed within 8 weeks, so good glycemic control should be obtained prior to conception. Unfortunately, major congenital malformations due to poor glucose control remain the leading cause of mortality and serious morbidity in infants of mothers with type 1 or type 2 diabetes. For women with diabetes mellitus controlled by lifestyle measures alone, conversion to insulin as soon as the pregnancy is confirmed is appropriate. For women with polycystic ovary disease who ovulate and become pregnant with insulin-sensitizer therapy such as metformin, conversion to insulin is recommended as soon as pregnancy is confirmed, but whether to continue the insulin sensitizer is a controversial topic. For example, in polycystic ovary disease insulin sensitizers are often needed to become pregnant, so some clinicians feel they should be continued. In Europe, metformin is sometimes used in pregnancy for type 2 DM, but the use is much lower in the United States. Metformin can cross the placenta, but this does not necessarily mean harm to the fetus. Patients previously treated with insulin may need intensification of their regimen to achieve therapeutic goals. Normal pregnancy is associated with a decrease in the blood glucose concentration as fuel is diverted to the fetus. Pregnant patients will be ingesting both meals and snacks daily. SMBG is generally intensified to try to reach glycemic targets and reduce fetal and maternal morbidity. Whether preprandial or postprandial glucose concentrations should be the target of therapy is hotly debated. Ketosis should be avoided, requiring urine monitoring for ketones in the morning and if the blood sugar is >200 mg/dL.

There has been some concern about the safety of insulin analogs in pregnancy, both for fetal development and advancement of microvascular complications. One study has shown no increase in retinopathy or progression of same with the use of insulin lispro in pregnancy.

SPECIAL TOPICS

Prevention of Diabetes Mellitus

12 Efforts to prevent type 1 DM with immunosuppressives,[103] niacinamide, injected insulin,[104] or oral insulin therapy[105] have been unsuccessful. The Diabetes Prevention Program[106] confirmed that modest weight loss in association with exercise can have a dramatic impact on insulin sensitivity and the conversion from impaired glucose tolerance to type 2 diabetes. In this study approximately 2,000 individuals with impaired glucose tolerance were randomized to lifestyle changes (diet, exercise, and weight loss) versus usual care. The study, which was originally planned to be ongoing for 5 years, was stopped after 2.8 years because the results were so conclusive. The usual care group developed diabetes at the rate of 11% each year. The lifestyle arm developed diabetes at a rate of 5% per year, a 58% reduction in the risk of developing diabetes.[106] Surprisingly, a modest amount of diet and exercise yielded impressive results. The exercise program in the lifestyle group was walking 30 minutes 5 days each week. The mean weight loss over the 2.8-year study period was only 8 pounds. Similar results were seen in the Finnish Diabetes Study.[107] In the Diabetes Prevention Program[106] discussed above, approximately 1,000 of the study patients were randomized to metformin therapy. Metformin therapy reduced the risk of developing type 2 DM by 31% compared to usual care and resulted in a 4-pound weight loss [106] Interestingly, young and overweight individuals on metformin had a greater reduction in the risk of developing diabetes than normal weight and older study patients.[106]

Metformin and acarbose[64] appear to mostly be treating early diabetes, because when the drugs were stopped, diabetes rates were close to the conversion rates for placebo. In contrast, the TRIPOD study[108] evaluated the ability of troglitazone to prevent the development of diabetes in women with a history of gestational diabetes. The rate of development of diabetes in the placebo arm of the study was approximately 12% per year, compared with about 5% in the treatment group. Total preservation of β-cell function was demonstrated over a 5-year period in women who had near-normal β-cell function at baseline and who initially responded to the drug.[108] The preservation of β-cell function was observed for at least 8 months after the drug had been discontinued. The DREAM trial evaluated rosiglitazone and/or ramipril treatment for the delay or prevention of type 2 DM in impaired glucose tolerant subjects.[109,110] Rosiglitazone 8 mg daily, over approximately 3 years, reduced the incidence of type 2 diabetes by 60%. In addition, a 37% nonsignificant increase in cardiovascular events was reported. Ramipril 15 mg daily did not significantly prevent the conversion to diabetes. It is possible that longer exposure could have made a difference, but the study was stopped prematurely. In contrast, valsartan, and angiotensin-receptor blocker (ARB), administered for 5 years was recently reported to reduce the risk of progression from impaired glucose tolerance to type 2 DM by 14%. The ACT Now trial used pioglitazone 45 mg daily in an IGT population and found an 81% reduction in the risk of development of diabetes over 3 years. It should be noted that no pharmacologic agents are currently FDA approved or recommended for prevention of type 2 diabetes, although the ADA recommends metformin in conjuction with lifestyle changes if the patient is younger, obese, has a family history of diabetes, dyslipidemia, hypertension, or a HbA_{1c} >6%.[111] The next step is discussions with the FDA to decide how and if medications to prevent diabetes can be approved for this indication.

CLINICAL CONTROVERSY

Diabetes mellitus is associated with a substantially higher risk of morbidity and mortality. Pharmacologic prevention or delay of type 2 DM has been widely discussed since the release of the Diabetes Prevention Program results. Though lifestyle changes were effective, with a 58% lower relative risk of progression to diabetes, metformin 850 mg twice a day reduced the risk by 31%, and was essentially as effective as diet and exercise in

young/obese subjects. Pioglitazone, rosiglitazone, acarbose, and even orlistat all have, to one extent or another, been able to delay the onset of type 2 DM. Despite these data, there are no FDA-approved drugs for the delay or prevention of diabetes. The ADA-recommended medications, in conjuction with lifestyle, for the delay or prevention of type 2 DM include metformin. It should be remembered that medications require monitoring and can have serious side effects. Many feel they are simply treating diabetes early, as there is considerable β-cell dysfunction documented in early impaired glucose tolerant subjects. Other than troglitazone, which is not on the market, no medication has clearly shown β-cell preservation. It is logical to try to use medications if they alter the decline of β-cell function, but this is currently off-label use and any attempt to use medication in these situations should be clearly and frankly discussed with the patient.

Patient Education

13 It is not satisfactory to give patients with DM brief instructions with a few pamphlets and expect them to manage their disease adequately.[112] Thinking that diabetes education is limited to one or two encounters is misguided; education is a lifetime exercise. Successful treatment of DM involves lifestyle changes for the patient (e.g., medical nutrition therapy, physical activity, self-monitoring of blood glucose and possibly of urine for ketones, recognition of hyper- and hypoglycemia, and taking prescribed medications). The American Association of Diabetes Educators (AADE) has developed the AADE7 self-care behaviors of healthy eating, being active, monitoring, taking medication, problem solving, reducing risk, and healthy coping, which is a good starting framework for patient discussions. The patient must be involved in the decision-making process and must learn as much about the disease and associated complications as possible. Emphasis should be placed on the evidence that indicates that complications can be prevented or minimized with glycemic control and management of risk factors for cardiovascular disease. Recognition of the need for proper patient education to empower them into self-care has generated programs for certification in diabetes education for pharmacists. Certified diabetes educators (CDEs) must document their patient education hours and sit for a certification examination that assesses the knowledge, tasks, and skills of an educator in order to become certified. An increasing number of nurses, pharmacists, dietitians, and physicians are becoming CDEs to document to the public that they meet a minimum standard for diabetes education, and to fulfill quality initiatives in meeting guidelines for education recognition. Being a CDE does not guarantee reimbursement of services, and CDEs who are not dietitians will often need to become part of a recognized program to obtain reimbursement. Currently the AADE and ADA have accreditation programs. 14

TREATMENT OF CONCOMITANT CONDITIONS AND COMPLICATIONS

Retinopathy

Patients with established retinopathy should see an ophthalmologist or optometrist trained in diabetic eye disease. A dilated eye exam is required to fully evaluate diabetic eye disease. Early background retinopathy may reverse with improved glycemic control. More advanced retinopathy will not regress with improved glycemia, and may actually worsen with short-term improvements in glycemia. Studies are under way to determine whether medical therapy independent of glucose control will prevent the development of advanced retinopathy. Laser photocoagulation has markedly improved sight preservation in diabetic patients.

Neuropathy

Peripheral neuropathy is the most common complication seen in type 2 DM patients in outpatient clinics.[113] Paresthesias, numbness, or pain may be the predominant symptom. The feet are involved far more often than the hands. Improved glycemic control may alleviate some of the symptoms. If neuropathy is painful, symptomatic therapy is empiric, including low-dose tricyclic antidepressants, anticonvulsants (gabapentin, pregabalin, carbamazepine, and maybe phenytoin), duloxetine, venlafaxine, topical capsaicin, and various pain medications, including tramadol and nonsteroidal antiinflammatory drugs. Recently, another anticonvulsant, topiramate, has shown promise in the reduction of symptoms, with the positive side effect of weight loss in type 2 diabetes patients, though tolerability is problematic. The numb variant of peripheral neuropathy is not treated with medication. Clinical manifestations of diabetic autonomic neuropathy include resting tachycardia, exercise intolerance, orthostatic hypotension, constipation, gastroparesis, erectile dysfunction, sudomotor dysfunction (anhidrosis, heat intolerance, gustatory sweating, and/or dry skin), impaired neurovascular function, and hypoglycemic autonomic failure. Gastroparesis can be a severe and debilitating complication of DM. Improved glycemic control, discontinuation of medications that slow gastric motility, and the use of metoclopramide (preferably for only a few weeks at a time) or erythromycin may be helpful. Gastric pacemakers as therapeutic hardware are rarely used, though available, and cisapride, removed from the market several years ago, is still available for compassionate use. Orthostatic hypotension may require pharmacologic management with mineralocorticoids or adrenergic agonist agents. In severe cases, supine hypertension is extreme, mandating that the patient sleep in a sitting or semirecumbent position. Patients with cardiac autonomic neuropathy are at a higher risk for silent MI and mortality. The hallmark of diabetic diarrhea is its nocturnal occurrence. Diabetic diarrhea frequently responds to a 10- to 14-day course of an antibiotic such as doxycycline or metronidazole. In more unresponsive cases, octreotide may be useful. Erectile dysfunction is common in diabetes, and initial treatment should include a trial of one of the oral medications currently available to treat erectile dysfunction. People with diabetes often require the highest doses of these medications to have an adequate response. Sudomotor dysfunction, as earlier defined, results in loss of sweating and resultant dry, cracked skin. Use of hydrating creams and ointments is needed.

Microalbuminuria and Nephropathy

Diabetes mellitus, particularly type 2 DM, is the biggest contributor statistically to the development of endstage renal disease in the United States.[114] The American Diabetes Association recommends a screening urinary analysis for albumin at diagnosis in persons with type 2 DM. Precise onset of type 2 DM can rarely be ascertained, and patients will often present at diagnosis with microvascular complications. In type 1 DM, microalbuminuria rarely occurs with short duration of disease or before puberty. Screening individuals with type 1 DM should begin with puberty and after 5 years' disease duration. There are three methods for assessing microalbuminuria: (1) measurement of the urine albumin:creatinine ratio in a random spot collection (preferably the first morning void); (2) 24-hour timed collection; and (3) timed (e.g., 4- or 10-hour overnight) collection. Microalbuminuria on a spot urine specimen is defined as a

ratio of 30 to 300 mg/g albumin:creatinine. On timed collections, microalbuminuria is defined as 30 to 300 mg/24 hours or an albumin excretion rate of 20 to 200 mcg/min. Because of day-to-day variability, microalbuminuria should be confirmed on at least two of three samples over 3 to 6 months. Additionally, when assessing urine protein or albumin, conditions that may cause transient elevations in urinary albumin excretion should be excluded. These conditions include intense exercise, recent urinary tract infections, hypertension, short-term hyperglycemia, heart failure, and acute febrile illness.[114]

In type 2 DM, the presence of microalbuminuria is a strong risk factor for macrovascular disease and is frequently present at the time of diagnosis. Microalbuminuria is a weaker predictor for future kidney disease in type 2 versus type 1 DM.

Glucose and blood pressure control are most important for the prevention of nephropathy, and blood pressure control is the most important for retarding the progression of established nephropathy. ACE inhibitors and ARBs, considered first-line recommended treatment modalities, have shown efficacy in preventing the clinical progression of renal disease in patients with type 2 DM.[115–117] Diuretics frequently are necessary due to the volume-expanded state of the patient and are recommended second-line therapy. The American Diabetes Association and the National Kidney Foundation blood pressure goal of <130/80 mm Hg can be difficult to achieve. Three or more antihypertensives are often needed to treat to goal blood pressures.

Peripheral Vascular Disease and Foot Ulcers

Claudication and nonhealing foot ulcers are common in type 2 DM patients.[118] Smoking cessation, correction of lipid abnormalities, and antiplatelet therapy are important strategies in treating claudicants. Cilostazol may be useful for reducing intermittant claudication symptoms in select patients. Revascularization is successful in selected patients, though small vessel disease that cannot be bypassed is common in diabetes. Local débridement and appropriate footwear and foot care are vitally important in the early treatment of foot lesions. In more advanced lesions, topical treatments may be of benefit. Diabetic foot care is an excellent example of the adage, "an ounce of prevention is worth a pound of cure."

Coronary Heart Disease

11 The risk for coronary heart disease (CHD) is 2 to 4 times greater in diabetic patients than in nondiabetic individuals. CHD is the major source of mortality in patients with DM. Recent studies suggest that multiple risk factor intervention (lipids, hypertension, smoking cessation, and antiplatelet therapy)[8] will reduce the burden of excess macrovascular events. The ADA recommends aspirin therapy in all secondary prevention situations, and if allergic to aspirin, consider clopidogrel. Recent evidence in primary prevention studies of antiplatelet therapy in type 2 DM have not shown benefit. The ADA currently recommends that if the 10-year risk of CVD is at least 10%, or the patient is at your judgment high risk, or in women at least 50 years old or men at least 60 years old, primary prevention antiplatelet therapy can be considered. Epidemiologic data suggest that CHD prevention guidelines for type 2 DM apply equally to patients with type 1 DM.[8] β-Blocker therapy supplies an even greater protection from recurrent CHD events in diabetic patients than in nondiabetic subjects. Masking of hypoglycemic symptoms is a greater problem in type 1 DM patients than in patients with type 2 DM.

Lipids The Collaborative Atorvastatin Diabetes Study (CARDS) randomized diabetes subjects with no documented cardiovascular disease to atorvastatin 10 mg daily (n = 1,428) or placebo (n = 1,410). The trial was stopped 2 years early (mean duration of follow-up was 3.9 years) after meeting the primary efficacy endpoint of major cardiovascular events, which were reduced by 37% ($P = 0.001$). All-cause death was reduced 27% ($P = 0.059$), and potentially could have had its significance influenced by the early stoppage of the trial.[119] The Heart Protection Study randomized 5,963 patients age >40 years with diabetes and total cholesterol >135 mg/dL. A significant 22% reduction (95% CI, 13–30) in the event rate for major cardiovascular events was seen with simvastatin 40 mg/day. This was evident even at lower LDL levels (<116 mg/dL), and suggests that ~30% to 40% reduction in LDL levels regardless of starting LDL levels may be appropriate.[120] The proper use of fibrates in diabetes continues to be controversial. The diabetic subgroup in the Veterans Administration HDL Intervention Trial (VA-HIT) of CHD patients with low HDL-C and low LDL-C showed approximately 22% reduction in CHD events in diabetic patients with known CHD when HDL-C was increased by approximately 6% by gemfibrozil.[121] The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) was conducted in 9,795 subjects (22% with previously documented CVD) with type 2 DM given fenofibrate 200 mg daily or placebo. A relative reduction of 11% ($P = 0.16$) was seen in any coronary event in conjunction with a slight increase in the risk of all-cause mortality (0.7%; $P = 0.18$). Reasons for this have been speculated on, including the increased use of statins in the placebo group, but continue to be controversial.[122] On subset analysis, only subjects without CVD had a significant reduction in CVD events. The lipid arm of the ACCORD[123] reported on 5,518 subjects randomized to fenofibrate or placebo given with low-dose simvastatin (~20 mg/day). Fenofibrate addition did not significantly lower cardiovascular events (0.92; 95% CI, 0.79–1.08). On subgroup analysis, women had a 30% higher risk of adverse cardiovascular outcomes, but this was not seen in the FIELD trial. In addition, the only subjects who had a lowering of CVD risk were subjects with high triglycerides combined with low HDL-C.

The National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP)[124] guidelines classify the presence of DM as a CHD risk equivalent, and therefore recommend that LDL-C be lowered to <100 mg/dL. An optional LDL goal in high-risk DM patients, such as those who already have CHD, has been updated to <70 mg/dL.[125] Unlike previous guidelines, more consideration is now given to HDL-C and triglycerides. The primary target is the treatment of LDL-C. After the LDL-C goal is reached (usually with a statin), via NCEP-ATP, triglycerides are possibly considered for pharmacologic management, assuming unresponsiveness to glycemic control efforts, weight management, and exercise. In such situations, a non–HDL-C goal is established (a surrogate for all apolipoprotein B–containing particles). The non–HDL-C goal for patients with DM is <130 mg/dL. Niacin or a fibrate can be added to reach that goal if triglycerides are 201 to 499 mg/dL. NCEP-ATP states that niacin or a fibrate can also be added if the LDL-C goal is reached, but if the patient has low HDL-C (<40 mg/dL), fibrates have very little, if any positive effect on HDL-C. Patients with marked hypertriglyceridemia (≥500 mg/dL) are at risk for pancreatitis. Efforts to reduce triglycerides with glycemic control, elimination of other secondary causes (including medications), and drug therapy (fibrate and/or niacin) are effective treatment strategies. The ADA also recommends similar LDL goals, but places raising HDL as the second priority (Table 83–16). The definitive role of pharmacologic therapy of HDL-C and/or hypertriglyceridemia in type 2 DM patients (beyond that seen with statin therapy) has yet to be proven in clinical trials, but is leaning heavily toward HDL-C being a very important second priority for the prevention of CVD.

TABLE 83-16 Classification of Lipid and Lipoprotein Levels in Adults[8,124,125]

Parameter	Goal		Treatment (In Order of Preference)
LDL cholesterol	<100 mg/dL <70 mg/dL[a]		Lifestyle; HMG-CoA reductase inhibitors; cholesterol absorption inhibitor; niacin or fenofibrate
HDL cholesterol	Men >40 mg/dL	Women >50 mg/dL	Lifestyle; nicotinic acid; fibric acid derivatives
Triglycerides	<150 mg/dL		Lifestyle; glycemic control; fibric acid derivatives; high-dose statins (in those with high LDL)

HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein.
[a]May be optimal goal in patients with preexisting cardiovascular disease.

CLINICAL CONTROVERSY

The use of fibric acid derivatives and ezetimibe continues to be controversial in the treatment of dyslipidemia in diabetes patients. The FIELD trial using fenofibrate did not result in similar CVD reductions that have been documented in diabetes statin trials. The ACCORD lipid arm in type 2 DM patients added fenofibrate to low-dose simvastatin and did not lower the risk of CVD. The VA-HIT trial using gemfibrozil, though a subset, has shown a reduction in CVD outcomes. Fibric acid derivatives should be considered at least third-line therapy, unless triglycerides are high enough that LDL-C is not reported. It is reasonable to consider use of gemfibrozil as the first fibric acid derivative in diabetes subjects based on the FIELD and ACCORD data. If the drug–drug interaction of a statin with a fibric acid derivative is of paramount importance to the clinician, fenofibrate can be considered. Ezetimibe, and whether it can reduce CVD, continues to be controversial. Colesevelam, which does not have CVD outcomes in diabetes patients, may be a better choice as it will decrease LDL-C in conjuction with a statin, and has the added benefit of a modest reduction in HbA_{1c}. Neither should be considered until statin therapy is optimized.

Hypertension

The role of hypertension in increasing microvascular and macrovascular risk in patients with DM has been confirmed in the UKPDS[70] and Hypertension Optimization Treatment[126] trials. The American Diabetes Association recommends aggressive goals for blood pressure (<130/80 mm Hg) in patients with DM.[8] The ACCORD blood pressure arm studied type 2 DM patients, with a goal of achieving a systolic blood pressure of either <120 mm Hg (achieved 119 mm Hg) or <140 mm Hg (133 mm Hg achieved).[127] The lower pressure group did not have lower CVD or renal outcomes, but did lower the risk of stroke. ACE inhibitors and ARBs are generally recommended for initial therapy, as they have shown to be cardioprotective, and likely have special renal protection. Many patients require multiple agents, on average three agents, to obtain goals, so diuretics, calcium channel blockers, and β-blockers frequently are useful as second and third agents. African Americans need special consideration. African Americans receive renoprotection from ACE inhibitors or ARBs, but as a population may lower blood pressure slightly less with these agents. It is recommended that combination therapy with a diuretic or calcium channel blocker be considered as first-line therapy. After initial therapy, which agent to add next is still controversial. Blood pressure goals are generally more difficult to achieve than glycemic goals or lipid goals in most diabetic patients.

CLINICAL CONTROVERSY

The systolic blood pressure target in diabetes may be in flux. Results of the ACCORD trial did not find improved cardiovascular or renal outcomes in patients who achieved a systolic blood pressure of ~120 mm Hg versus ~130 mm Hg. The lowering of the systolic blood pressure did lower the risk of stroke. Further analysis is warranted prior to drastic changes in blood pressure goals. Initial therapy choices for hypertension in diabetes mellitus usually includes ACE inhibitors or ARBs. In the diabetic subset of the ALLHAT, diuretics have shown equivalent cardiovascular protection to an ACE inhibitor. If ACE inhibitors and ARBs are not more cardioprotective, then why use them first line? Both have proven special renoprotective effects. If a clinician is meticulous in their yearly monitoring for microalbuminuria, it is possible that a diuretic or calcium channel blocker could be started as first-line therapy. As clinical inertia in yearly microalbuminuria screening is often documented, ACE inhibitors or ARBs are give first-line status. ACE inhibitors, ARBs, β-blockers, diuretics, or calcium channel blockers have all shown benefit in prevention of cardiovascular outcomes. Choice of monotherapy may not be important, as an average of two to three antihypertensive medications are needed to reach blood pressure goals.

Transplantation

Whole pancreas and islet cell transplantation are still relatively experimental procedures in patients with type 1 DM; those with endstage renal disease also receive kidney transplantation.[128]

PHARMACOECONOMIC CONSIDERATIONS

As described in the introduction, the direct and indirect costs of DM are substantial. Much of the indirect costs are related to loss of productivity due to the significant morbidity (hospitalizations, loss of vision, lower extremity amputations, kidney failure, and cardiovascular events) associated with the disease. For a disease that affects about 8% of the population, it is responsible for 11% to 12% of health expenditures (in 2007, direct $116 billion, indirect $58 billion[1]). With evidence from the DCCT and UKPDS to support intensive blood glucose control to reduce the risk of complications, the question of cost-effectiveness comes into play.

An economic model based on the DCCT approximates that 120,000 persons in the United States would meet criteria for intensive intervention. The cost of implementing intensive therapy over the lifetime of the population is estimated at $4 billion. The benefits of this strategy are net gains of 920,000 years of sight, 691,000 years free from endstage renal disease, and 678,000 years free from lower extremity amputations. The incremental cost per year of life gained is $28,661.[129] This is well within the limits of a cost-effective strategy and compares favorably to treatment of high blood pressure or hypercholesterolemia.

Economic analysis of intensive therapy for type 2 DM is more complex. Outcomes must also factor in the burden of CVD as the major cause of mortality. One model analyzed the health benefits and economics of treating type 2 DM with the goal of achieving normoglycemia, but using outcomes based on the DCCT trial results. Accounting

for the prevalence of CVD in type 2 DM, an estimate of $16,002 incremental cost per quality-adjusted life-year gained was obtained. The limitation of this analysis is that while the UKDPS did demonstrate an improvement in diabetes-related outcomes, the overall efficacy on microvascular disease complications was not mirrored by the DCCT.

Two economic analyses were performed on data generated from the UKPDS, one assessing cost-effectiveness of an intensive blood glucose control policy in type 2 DM, and the other assessing improved blood pressure control in hypertensive patients with type 2 DM. In the first analysis, outcome was measured as the incremental cost per event-free year gained within the trial. Based on trial outcomes and assumptions, the incremental cost in the intensive treatment group per event-free year gained is $1,366. While intensive treatment costs were higher, the cost per event-free year gained appears cost-effective. The second analysis showed the incremental cost per extra year free from microvascular and macrovascular endpoints from intensive blood pressure control in a standard clinical practice model to be $1,498. The incremental cost per life-year gained was estimated at $619, again, demonstrating the cost-effectiveness of intensive intervention.[130,131]

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

A comprehensive pharmaceutical care plan for the patient with DM will integrate considerations of goals to optimize blood glucose control and protocols to screen for, prevent, or manage microvascular and macrovascular complications. In terms of standards of care for persons with DM, one can review the document published by the American Diabetes Association that outlines initial and ongoing assessments for patients with DM.[8] The major performance measure by the National Committee for Quality Assurance (NCQA), such as Health Plan Employer Data and Information Set (HEDIS), should assess the ability to meet current standards of care and recognize the minimal treatment goals for glycemia, lipids, and hypertension, and provide targets for monitoring and adjusting pharmacotherapy as discussed in various sections above. Publicly reported quality measures continue to move closer to current guidelines, but lack the ability to differentiate reasons why a patient is not controlled. Glycemic control (tested minimally yearly; HbA_{1c} <8% is good control and HbA_{1c} >9% is poor control), lipid (percentage of patients with LDL <100 mg/dL), and hypertension (percentage of patients with blood pressure <130/80 mm Hg, but also with blood pressure <140/90) are NCQA-based measures. Glycemic control is paramount in managing type 1 or type 2 DM, but as readily identified from the above discussion, it requires frequent assessment and adjustment in diet, exercise, and pharmacologic therapies. The ADA also has clinical practice recommendations that are widely cited and followed.[8] Minimally, HbA_{1c} should be measured twice a year in patients meeting treatment goals on a stable therapeutic regimen. Quarterly assessments are recommended for those whose therapy has changed or who are not meeting glycemic goals. Fasting lipid profiles should be obtained as part of an initial assessment and thereafter at each follow-up visit if not at goal, annually if stable and at goal, or every 2 years if the lipid profile suggests low risk. Documenting regular frequency of foot exams (each visit), urine albumin assessment (annually), dilated ophthalmologic exams (yearly or more frequently with identified abnormalities), and office visits for follow-up are also important. Assessment for pneumococcal vaccine administration (and one time revaccination recommended in individuals at least 65 years old), annual administration of influenza vaccine, and routine assessment for and management of other cardiovascular risks (e.g., smoking and antiplatelet therapy) are components of preventive medicine strategies. The multiplicity of assessments for each patient visit are likely to be better facilitated utilizing an integrative computer program and electronic medical record, standardized progress note forms, or flow sheets, which assist the clinician in identifying whether the patient has met standards of care in the frequency of monitoring and achievement of defined targets of therapy.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
ADA: American Diabetes Association
ALT: alanine aminotransferase
ARB: angiotensin-receptor blockers
BMI: body mass index
CDE: certified diabetes educator
CHD: coronary heart disease
CVD: cardiovascular disease
CSII: continuous subcutaneous insulin infusion
CYP450: cytochrome P450
DCCT: Diabetes Control and Complications Trial
DM: diabetes mellitus
FFA: free fatty acid
GCT: glucose challenge test
GDM: gestational diabetes mellitus
HbA_{1c}: hemoglobin A_{1c}
HDL-C: high-density lipoprotein cholesterol
IFG: impaired fasting glucose
IGT: impaired glucose tolerance
LADA: latent autoimmune diabetes in adults
LDL-C: low-density lipoprotein cholesterol
MODY: maturity onset diabetes of youth

CHAPTER 84

Thyroid Disorders

JACQUELINE JONKLAAS AND ROBERT L. TALBERT

KEY CONCEPTS

1. The molecular biology of the thyroid hormones and their receptors has provided an in-depth understanding of the various mutations that give rise to hyper- and hypothyroidism.
2. Thyrotoxicosis is most commonly caused by Graves's disease, which is an autoimmune disorder in which thyroid-stimulating antibody (TSAb) directed against the thyrotropin receptor elicits the same biologic response as thyroid-stimulating hormone (TSH).
3. Hyperthyroidism may be treated with antithyroid drugs such as propylthiouracil (PTU) or methimazole (MMI), radioactive iodine (RAI: ^{131}I), or surgical removal of the thyroid gland; selection of the initial treatment approach is based on patient characteristics such as age, concurrent physiology (e.g., pregnancy), comorbidities (e.g., chronic obstructive lung disease), and convenience.
4. PTU and MMI reduce the synthesis of thyroid hormones and are similar in efficacy and adverse effects, but their dosing ranges differ by 10-fold.
5. Response to PTU and MMI is seen in 4 to 6 weeks with a maximal response in 4 to 6 months; treatment usually continues for 1 to 2 years, and therapy is monitored by clinical signs and symptoms and by measuring the serum concentrations of TSH and free thyroxine (T_4).
6. Many patients choose to have ablative therapy with ^{131}I rather than undergo repeated courses of PTU or MMI; most patients receiving RAI eventually become hypothyroid and require thyroid hormone supplementation.
7. Adjunctive therapy with β-blockers controls the adrenergic symptoms of thyrotoxicosis but does not correct the underlying disorder; iodine may also be used adjunctively in preparation for surgery and acutely for thyroid storm.
8. Hypothyroidism is most often due to an autoimmune disorder known as *Hashimoto's thyroiditis*, and the drug of choice for replacement therapy is levothyroxine.
9. Monitoring of levothyroxine replacement therapy is achieved by observing clinical signs and symptoms and by measuring the TSH (elevated for underreplacement, suppressed for overreplacement).

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Thyroid hormones affect the function of virtually every organ system. In the child, thyroid hormone is critical for normal growth and development. In the adult, the major role of thyroid hormone is to maintain metabolic stability. Substantial reservoirs of thyroid hormone in the thyroid gland and blood provide constant thyroid hormone availability. In addition, the hypothalamic–pituitary–thyroid axis is exquisitely sensitive to small changes in circulating thyroid hormone concentrations, and alterations in thyroid hormone secretion maintain peripheral free thyroid hormone levels within a narrow range. Patients seek medical attention for evaluation of symptoms due to abnormal thyroid hormone levels or because of diffuse or nodular thyroid enlargement.

THYROID HORMONE PHYSIOLOGY

THYROID HORMONE SYNTHESIS

1 The thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) are formed on thyroglobulin, a large glycoprotein synthesized within the thyroid cell (Fig. 84–1). Because of the unique tertiary structure of this glycoprotein, iodinated tyrosine residues present in thyroglobulin are able to bind together to form active thyroid hormones.[1]

Iodide is actively transported through the basolateral membrane via a Na^+/I^- symporter from the extracellular space into the thyroid follicular cell against an electrochemical gradient, driven by the coupled transport of sodium.[2] Structurally related anions such as SCN^- (thiocyanate), ClO_4^- (perchlorate), and TcO_4^- (pertechnetate) are competitive inhibitors of iodine transport.[3] In addition,

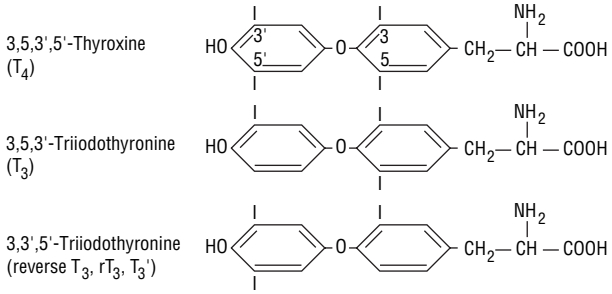

FIGURE 84-1. Structure of thyroid hormones.

TABLE 84-1 Thyroid Hormone Synthesis and Secretion Inhibitors

Mechanism of Action	Substance
Blocks iodide transport into the thyroid	Bromine
	Fluorine
	Lithium (?)
Impairs organification and coupling of thyroid hormones	Thionamides
	Sulfonylureas
	Sulfonamide (?)
	Salicylamide (?)
	Antipyrine (?)
Inhibits thyroid hormone secretion	Iodide (large doses), lithium

bromine, fluorine, and under certain circumstances lithium, block iodide transport into the thyroid (Table 84–1). Inorganic iodide that enters the thyroid follicular cell is ushered through the cell to the apical membrane, where it is transported into the follicular lumen by at least two efflux channels.[4,5] Located on the luminal side of the apical membrane, thyroid peroxidase oxidizes iodide and covalently binds the organified iodide to tyrosine residues of thyroglobulin (Fig. 84–2). It is interesting that although salivary glands and the gastric mucosa are able to actively transport iodide, they are unable to effectively incorporate iodide into proteins given the lack of similar oxidizing machinery. Similarly, when tyrosine molecules are iodinated on proteins other than thyroglobulin, they lack the proper tertiary structure needed to allow the formation of active thyroid hormones.

The iodinated tyrosine residues monoiodotyrosine (MIT) and diiodotyrosine (DIT) combine to form iodothyronines (Fig. 84–3). Thus, two molecules of DIT combine to form T_4, whereas MIT and DIT constitute T_3. In addition to its role in iodine organification, the hemoprotein thyroid peroxidase also catalyzes the formation of iodothyronines (coupling).

Iodine deficiency causes an increase in the ratio of MIT to DIT in thyroglobulin and leads to a relative increase in the production of T_3.[6] Because T_3 is more potent than T_4, the increase in T_3 production in iodine-depleted areas may be beneficial. The thionamide drugs

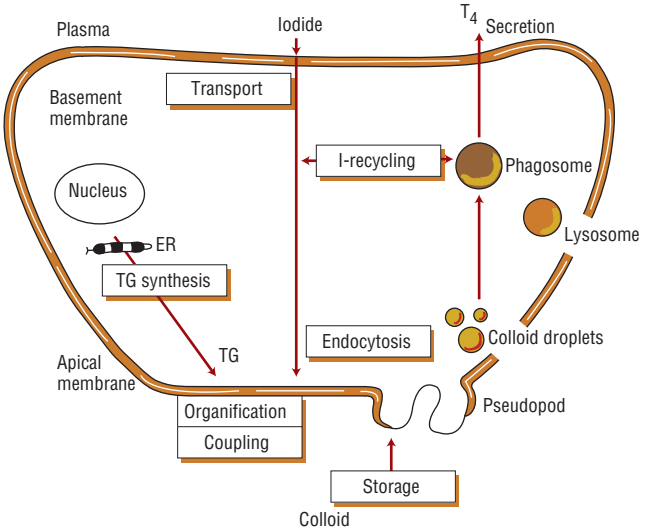

FIGURE 84-2. Thyroid hormone synthesis. Iodide is transported from the plasma, through the cell, to the apical membrane, where it is organified and coupled to the thyroglobulin (TG) synthesized within the thyroid cell. Hormone stored as colloid reenters the cell through endocytosis and moves back toward the basal membrane, where thyroxine (T_4) is secreted.

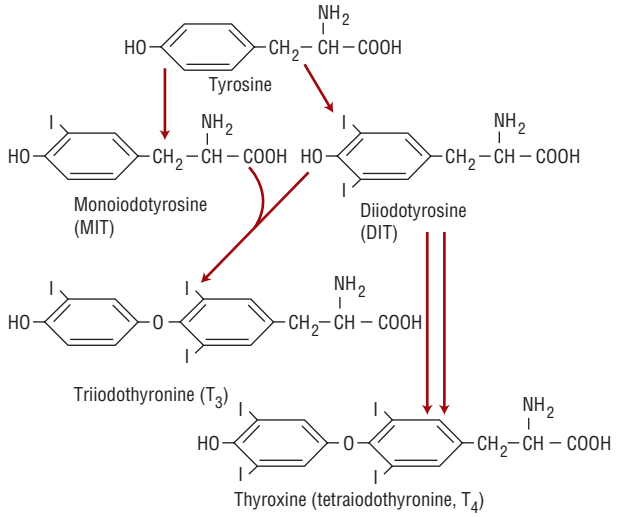

FIGURE 84-3. Scheme of coupling reactions. After tyrosine is iodinated to form monoiodotyrosine (MIT) or diiodotyrosine (DIT) (organification of the iodine), MIT and DIT combine to form triiodothyronine (T_3) or two molecules of DIT combine to form thyroxine T_4.

used to treat hyperthyroidism inhibit thyroid peroxidase and thus block thyroid hormone synthesis.

Thyroglobulin is stored in the follicular lumen and must reenter the cell, where the process of proteolysis liberates thyroid hormone into the bloodstream. Thyroid follicles active in hormone synthesis are identified histologically by columnar epithelial cells lining follicular lumens, which are depleted of colloid. Inactive follicles are lined by cuboidal epithelial cells and are replete with colloid. Both iodide and lithium block the release of preformed thyroid hormone, through poorly understood mechanisms.

T_4 and T_3 are transported in the bloodstream primarily by three proteins: thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin.[7] It is estimated that 99.96% of circulating T_4 and 99.5% of T_3 are bound to these proteins. However, only the unbound (free) thyroid hormone is able to diffuse into the cell, elicit a biologic effect, and regulate thyroid-stimulating hormone (TSH; also known as *thyrotropin*) secretion from the pituitary. Multiple functions have been ascribed to these transport proteins, including (1) assuring minimal urinary loss of iodide, (2) providing a mechanism for uniform tissue distribution of free hormone, and (3) transport of hormone into the central nervous system.

Whereas T_4 is secreted solely from the thyroid gland, less than 20% of T_3 is produced in the thyroid. The majority of T_3 is formed from the breakdown of T_4 catalyzed by the enzyme 5′-monodeiodinase found in extrathyroidal peripheral tissues. Because the binding affinity of nuclear thyroid hormone receptors is 10 to 15 times higher for T_3 than T_4, the deiodinase enzymes play a pivotal role in determining overall metabolic activity. Three different monodeiodinase enzymes are present in the body.[8] Of the enzymes that catalyze 5′-monodeiodination, type I enzymes are present in peripheral tissues, whereas type II enzymes are found in the central nervous system, pituitary, and thyroid. Type III enzymes, found in the placenta, skin, and developing brain, inactivate T_4 and T_3 by deiodinating the inner ring at the 5 position. The principal characteristics of these enzymes are listed in Table 84–2. T_4 may also be acted on by the enzyme 5′-monodeiodinase to form reverse T_3, but this accounts for a small component of hormone metabolism. Polymorphisms in the deiodinase genes may prove to be of clinical significance. For example, a polymorphism in the type I deiodinase leading to increased activity seems to be associated with an increased circulating ratio of free T_3 to free

TABLE 84-2 Properties of Iodothyronine 5′-Deiodinase Isoforms

Property	Type I	Type II	Type III
Effect of propylthiouracil	Increase	Decrease	Increase
Tissue localization	Thyroid, liver, kidney	Pituitary, thyroid, CNS, brown adipose tissue	Placenta, developing brain, skin
Preferred substrate	$rT_3 > T_4 > T_3$	$T_4 > T_3$	T_3(sulfate)$> T_4$
Physiologic role	Extracellular T_3 production for peripheral tissue	Intracellular T_3 production, especially for brain in hypothyroidism or iodine deficiency	Inactivation of T_4 and T_3
Developmental expression	Expressed latest in development; predominant deiodinase in adult	Expressed second; especially high in brain and brown adipose tissue	Expressed first; high in developing brain; may be important for fetal thyroid hormone metabolism

rT_3, reverse T_3; T_3, triiodothyronine; T_4, thyroxine.

T_4.[9] Reverse T_3 has no known significant biologic activity. T_3 is removed from the body by deiodinative degradation and through the action of sulfotransferase enzyme systems converting to T_3 sulfate and 3,3-diiodothyronine sulfates, thus facilitating enterohepatic clearance. Thyronamines are derivatives of thyroid hormone that are present in very low concentrations in human serum. The most studied thyronamine, 3-iodothyronamine, can theoretically be made from thyroxine by decarboxylation and deiodination. Administration of pharmacologic amounts of 3-iodothyronamine to animals has profound effects on temperature regulation and cardiac function, and shifts fuel metabolism from carbohydrates to lipids. However, a possible physiological role for thyronamines has yet to be determined.[10]

The growth and function of the thyroid are stimulated by activation of the thyrotropin receptor by TSH.[11] The receptor belongs to the family of G-protein–coupled receptors. The thyrotropin receptor is coupled to the α subunit of the stimulatory guanine-nucleotide–binding protein ($G_s\alpha$), activating adenylate cyclase and increasing the accumulation of cyclic adenosine monophosphate. Through this mechanism, TSH stimulates the expression of thyroglobulin and thyroid peroxidase genes as well as increases apical iodide efflux. Somatic activating mutations in the receptor are commonly seen in autonomously functioning thyroid nodules.[12] Rarely, germline activating mutations of the TSH receptor have been reported in kindreds with Leclere syndrome, and thyrotoxicosis can result from germline activating mutations in G-protein signaling in McCune-Albright syndrome.[11,13–15] Conversely, thyrotropin resistance would result from point mutations that prevent TSH binding, leading to abnormalities in the thyrotropin receptor–adenylate cyclase system and congenital hypothyroidism.[16,17] Individuals with this abnormality have high levels of TSH but decreased thyroglobulin levels and a normal or small gland.

Thyroid hormone receptors regulate the transcription of target genes in the presence of physiologic concentrations of T_3.[18] Unlike most other nuclear receptors, thyroid hormone receptors also actively regulate gene expression in the absence of hormone, typically resulting in an opposite effect. Thyroid receptors translocate from the cytoplasm to the nucleus, interact in the nucleus with T_3, and target genes and other proteins required for basal and T_3-dependent gene transcription. Thyroid receptors exist in three isoforms, TRβ2, TRβ1, and TRα1, with variation in the expression of each in differing tissues. There is interest in developing thyroid hormone analogues that selectively activate specific TR isoforms. Such agents could theoretically have targeted desirable effects such as stimulating energy expenditure without having adverse effects on other tissues.[19]

The production of thyroid hormone is regulated in two main ways. First, thyroid hormone is regulated by TSH secreted by the anterior pituitary. The secretion of TSH is itself under negative feedback control by the circulating level of free thyroid hormone and the positive influence of hypothalamic thyrotropin-releasing hormone (TRH). Second, extrathyroidal deiodination of T_4 to T_3 is regulated by a variety of factors including nutrition, nonthyroidal hormones, ambient temperatures, drugs, and illness.

THYROTOXICOSIS

Thyrotoxicosis results when tissues are exposed to excessive levels of T_4, T_3, or both.[20] In the National Health and Nutrition Examination Survey III, 0.7% of those surveyed who were not taking thyroid medications and had no history of thyroid disease had subclinical hyperthyroidism (TSH <0.1 milli-international units/L; and T_4 normal), and 0.5% had "clinically significant" hyperthyroidism (TSH <0.1 milli-international units/L; and T_4 >13.2 mcg/dL).[21] The prevalence of suppressed TSH peaked for people aged 20 to 39, declined in those 40 to 79, and increased again in those 80 or older. Abnormal TSH levels were more common among women than among men.

CLINICAL PRESENTATION OF THYROTOXICOSIS

General

- Signs and symptoms of hyperthyroidism affect multiple organ systems. Patients may have symptoms for an extended time period before the diagnosis of hyperthyroidism is made.

Symptoms

- The typical clinical manifestations of thyrotoxicosis include nervousness, anxiety, palpitations, emotional lability, easy fatigability, menstrual disturbances, and heat intolerance. A cardinal sign is loss of weight concurrent with an increased appetite.

Signs

- A variety of physical signs may be elicited including warm, smooth, moist skin, exophthalmos (in Graves's disease only), pretibial myxedema (in Graves's disease only), and unusually fine hair. Separation of the end of the fingernails from the nail beds (onycholysis) may be noted. Ocular signs that result from thyrotoxicosis include retraction of the eyelids and lagging of the upper lid behind the globe when the patient looks downward (lid lag). Physical signs of a hyperdynamic circulatory state are common and include tachycardia at rest, a widened pulse pressure, and a systolic ejection murmur. Gynecomastia is sometimes noted in men. Neuromuscular examination often reveals a fine tremor of the protruded tongue and outstretched hands. Deep tendon reflexes are generally hyperactive. Thyromegaly is usually present.

Diagnosis

- Low TSH serum concentration. Elevated free and total T_3 and T_4 serum concentrations, particularly in more severe disease.

- Elevated radioactive iodine uptake (RAIU) by the thyroid gland when hormone is being overproduced; suppressed RAIU in thyrotoxicosis due to thyroid inflammation (thyroiditis)

Other tests

- Thyroid stimulating antibodies (TSAb)
- Thyroglobulin
- Thyrotropin receptor antibodies

For the elderly patient and for the patient with very severe disease, anorexia may be present as well. Elderly patients are also more likely to develop atrial fibrillation with thyrotoxicosis than younger patients. The frequency of bowel movements may increase, but frank diarrhea is unusual. Palpitations are a prominent and distressing symptom, particularly in the patient with preexisting heart disease. Proximal muscle weakness is common and is noted on climbing stairs or in getting up from a sitting position. Women may note their menses are becoming scanty and irregular. Extremely thyrotoxic (thyrotoxic storm) patients may have tachycardia, heart failure, psychosis, hyperpyrexia, and coma.[22]

DIFFERENTIAL DIAGNOSIS

If the clinical history and examination do not provide pathognomonic clues to the etiology of the patient's thyrotoxicosis, measurement of the radioactive iodine uptake (RAIU) is critical in the evaluation (Table 84–3). The normal 24-hour RAIU ranges from 10% to 30% with some regional variation that is due to differences in iodine intake. An elevated RAIU indicates true hyperthyroidism, that is, the patient's thyroid gland is actively overproducing T_4, T_3, or both. Conversely, a low RAIU in the absence of iodine excess indicates that high levels of thyroid hormone are not a consequence of thyroid gland hyperfunction but are likely due to thyroiditis or hormone ingestion. The importance of differentiating true hyperthyroidism from other causes of thyrotoxicosis lies in the widely different prognosis and treatment of the diseases in these two categories. Therapy of thyrotoxicosis associated with thyroid hyperfunction is mainly directed at decreasing the rate of thyroid hormone synthesis, secretion, or both. Such measures are ineffective in treating thyrotoxicosis that is not the result of true hyperthyroidism, because hormone synthesis and regulated hormone secretion are already at a minimum.

CAUSES OF THYROTOXICOSIS ASSOCIATED WITH ELEVATED RAIU

TSH-Induced Hyperthyroidism

To better understand these syndromes, we must first review TSH biosynthesis and secretion. TSH is synthesized in the anterior pituitary as separate α- and β-subunit precursors. The α subunits from luteinizing hormone (LH), follicle-stimulating hormone (FSH), human chorionic gonadotropin (hCG), and TSH are similar, whereas the β subunits are unique and confer immunologic and biologic specificity. Free β subunits are devoid of receptor binding and biologic activity and require combination with an α subunit to express their activity. Criteria for the diagnosis of TSH-induced hyperthyroidism include (1) evidence of peripheral hypermetabolism, (2) diffuse thyroid gland enlargement, (3) elevated free thyroid hormone levels, and (4) elevated or inappropriately "normal" serum immunoreactive TSH concentrations. Because the pituitary gland is extremely sensitive to even minimal elevations of free T_4, a "normal" or elevated TSH level in any thyrotoxic patient indicates the inappropriate production of TSH.

TABLE 84-3 Differential Diagnosis of Thyrotoxicosis

Increased RAIU	Decreased RAIU
TSH-induced hyperthyroidism	Inflammatory thyroid disease
TSH-secreting tumors	Subacute thyroiditis
Selective pituitary resistance to T_4	Painless thyroiditis
Thyroid stimulators other than TSH[a]	Ectopic thyroid tissue
TSAb (Graves's disease)	Struma ovarii
hCG (trophoblastic diseases)	Metastatic follicular carcinoma
Thyroid autonomy	Exogenous sources of thyroid hormone
Toxic adenoma	Medication
Multinodular goiter	Food

hCG, human chorionic gonadotropin; RAIU, radioactive iodine uptake; TSAb, thyroid-stimulating antibodies; TSH, thyroid-stimulating hormone.

[a]The RAIU may be decreased if the patient has been recently exposed to excess iodine.

TSH-Secreting Pituitary Adenomas

TSH-secreting pituitary tumors occur sporadically and release biologically active hormone that is unresponsive to normal feedback control.[23] The mean age at diagnosis is around 40 years, with women being diagnosed more than men (8:7). These tumors may co-secrete prolactin or growth hormone; therefore the patients may present with amenorrhea/galactorrhea or signs of acromegaly. Most patients present with classic symptoms and signs of thyrotoxicosis. Visual-field defects may be present due to impingement of the optic chiasm by the tumor. Tumor growth and worsening visual-field defects have been reported following antithyroid therapy because lowering of thyroid hormone levels is associated with loss of feedback inhibition from high thyroid hormone levels.

Diagnosis of a TSH-secreting adenoma should be made by demonstrating lack of TSH response to TRH stimulation, inappropriate TSH levels, elevated α-subunit levels, and radiologic imaging; given the lack of routine availability of TRH, the other three criteria are essential. Note that some small tumors are not identified by MRI. Moreover, 10% of "normal" individuals may have incidental pituitary tumors or other benign focal lesions noted on pituitary imaging.

Transsphenoidal pituitary surgery is the treatment of choice for TSH-secreting adenomas. Pituitary gland irradiation is often given following surgery to prevent tumor recurrence. Bromocriptine and octreotide have been used to treat tumors, especially those that co-secrete prolactin.

Pituitary Resistance to Thyroid Hormone

Pituitary resistance to thyroid hormone (PRTH) refers to selective resistance of the pituitary thyrotrophs to thyroid hormone.[24] As nonpituitary tissues respond normally to thyroid hormone, patients experience the toxic peripheral effects of thyroid hormone excess. About twice as many women as men have been reported with this rare, probably familial syndrome. Multiple abnormalities have been reported in the initial 50 reported cases including schizophrenia (three patients), mental retardation (two patients), short fourth metacarpals (one patient), and Marfanoid habitus (one patient). About 90% of patients studied have an appropriate increase in TSH in response to TRH; conversely, the TSH will be suppressed by T_3 administration.

Patients with PRTH require treatment to reduce their elevated thyroid hormone levels. Determining the appropriate serum T_4 level is difficult because TSH cannot be used to evaluate adequacy of therapy. Any reduction in thyroid hormone carries the risk of inducing thyrotroph hyperplasia. Ideally, agents that suppress TSH secretion could be used to treat these individuals. Glucocorticoids, dopaminergic drugs, somatostatin and its analogs, and thyroid hormone analogs with reduced metabolic

activity have all been tried; given the ability of retinoid X receptor ligands to inhibit TSH production, drugs like bexarotene may have therapeutic benefit in PRTH. [25]

THYROID STIMULATORS OTHER THAN TSH

Graves's Disease

2 Graves's disease is an autoimmune syndrome that usually includes hyperthyroidism, diffuse thyroid enlargement, exophthalmos, and less commonly pretibial myxedema and thyroid acropachy (Fig. 84–4).[20,26,27] Graves's disease is the most common cause of hyperthyroidism, with a prevalence estimated to be 3 per 1,000 population in the United States. Hyperthyroidism results from the action of thyroid-stimulating antibodies (TSAb), which are directed against the thyrotropin receptor on the surface of the thyroid cell.[16,17] When these immunoglobulins bind to the receptor, they activate downstream G-protein signaling and adenylate cyclase in the same manner as TSH. Autoantibodies that react with orbital muscle and fibroblast tissue in the skin are responsible for the extrathyroidal manifestations of Graves's disease, and these autoantibodies are encoded by the same germline genes that encode for other autoantibodies for striated muscle and thyroid peroxidase.[28] Clinically, the extrathyroidal disorders may not appear at the same time that hyperthyroidism develops.

There is now compelling evidence that heredity predisposes the susceptible individual to development of clinically overt autoimmune thyroid disease in the setting of appropriate environmental and hormonal triggers. A role for gender in the emergence of Graves's disease is suggested by the fact that hyperthyroidism is approximately eight times more common in women than men. Other lines of evidence support a role for heredity. First, there is a well-recognized clustering of Graves's disease within some families. Twin studies in Graves's disease have revealed that a monozygotic twin has a 35% likelihood of ultimately developing the disease compared with a 3% likelihood for a dizygotic twin, resulting in estimation that the 79% of the predisposition to Graves's disease is genetic.[29] Second, the occurrence of other autoimmune diseases, including Hashimoto's thyroiditis, is also increased in families of patients with Graves's disease. Third, several studies have demonstrated an increased frequency of certain human leukocyte antigens (HLAs) for patients with Graves's disease. Differing HLA associations have been identified in the various ethnic groups studied. In whites, for example, the relative risk of Graves's disease in carriers of the HLA-DR3 haplotype is between 2.5 and 5, whereas lesser associations have been reported for HLA-B8 and the HLA-DQA*0501 allele.[30,31] As with other autoimmune conditions, certain polymorphisms of the T-cell immunoregulatory protein CTLA-4 have also been associated with Graves's disease. Despite these statistical associations, however, even detailed molecular genetic linkage studies have failed to identify specific genes responsible for the disease.[32]

The thyroid gland is diffusely enlarged in the majority of patients and is commonly 40 to 60 g (two to three times the normal size). The surface of the gland is either smooth or bosselated, and the consistency varies from soft to firm. For patients with severe disease, a thrill may be felt and a systolic bruit may be heard over the gland, reflecting the increased intraglandular vascularity typical of hyperplasia. Whereas the presence of any of the extrathyroidal manifestations of this syndrome, including exophthalmos, thyroid acropachy, or pretibial myxedema, in a thyrotoxic patient is pathognomonic of Graves's disease, most patients can be diagnosed on the basis of their history and examination of their diffuse goiter (see Fig. 84–4). An important clinical feature of Graves's disease is the occurrence of spontaneous remissions, albeit uncommon. The abnormalities in TSAb production may decrease or disappear over time in many patients.

The results of laboratory tests in thyrotoxic Graves's disease include an increase in the overall hormone production rate with a disproportionate increase in T_3 relative to T_4 (Table 84–4). In an occasional patient, the disproportionate overproduction of T_3 is

FIGURE 84-4. Features of Graves's disease. (A) Facial appearance in Graves's disease; lid retraction, periorbital edema, and proptosis are marked. (B) Thyroid dermopathy over the lateral aspects of the shins. (C) Thyroid acropachy. *(Reproduced with permission from Fauci AS, Kasper DL, Longo DL, Braunwald E, Havser SL, Jameson JL, Loscalzo J, eds. Harrison's Principles of Internal Medicine, 16th ed. New York: McGraw-Hill, 2005:2114.)*

TABLE 84-4 Thyroid Function Test Results in Different Thyroid Conditions

	Total T_4	Free T_4	Total T_3	T_3 Resin Uptake	Free Thyroxine Index	TSH
Normal	4.5–1 0.9 mcg/dL	0.8–2.7 ng/dL	60-181 ng/dL	22–34%	1.0–4.3 units	0.5–4.7 milli- international units/L
Hyperthyroid	↑↑	↑↑	↑↑↑	↑	↑↑↑	↓↓
Hypothyroid	↓↓	↓↓	↓	↓↓	↓↓↓	↑↑
Increased TBG	↑	Normal	↑	↓	Normal	Normal

TBG, thyroid-binding globulin; TSH, thyroid-stimulating hormone.

exaggerated, with the result that only the serum T_3 concentration is increased (T_3 toxicosis). The saturation of TBG is increased due to the elevated levels of serum T_4 and T_3, which is reflected in elevated values for the T_3 resin uptake. As a result, the concentration of free T_4, free T_3, and the free T_4 and T_3 indices are increased to an even greater extent than are the measured serum total T_4 and T_3 concentrations. The TSH level will be undetectable due to negative feedback by elevated levels of thyroid hormone at the pituitary.

For the patient with manifest disease, measurement of the serum free T_4 concentration (or total T_4 and T_3 resin uptake), total T_3, and the TSH value will confirm the diagnosis of thyrotoxicosis. If the patient is not pregnant, a 24-hour RAIU should be obtained if there is any diagnostic uncertainty, e.g., recent onset of symptoms or other factors suggestive of thyroiditis. An increased RAIU documents that the thyroid gland is inappropriately utilizing the iodine to produce more thyroid hormone at a time when the patient is thyrotoxic.

Hypokalemic periodic paralysis is a rare complication of hyperthyroidism commonly observed in Asian and Hispanic populations.[33] It presents as recurrent proximal muscle flaccidity ranging from mild weakness to total paralysis. The paralysis may be asymmetric and usually involves muscle groups that are strenuously exercised before the attack. Cognition and sensory perception are spared, whereas deep tendon reflexes are markedly diminished commonly. Hypokalemia results from a sudden shift of potassium from extracellular to intracellular sites rather than reduced total body potassium. High carbohydrate loads and exercise provoke the attacks. Treatment includes correcting the hyperthyroid state, potassium administration, spironolactone to conserve potassium, and propranolol to minimize intracellular shifts.

Trophoblastic Diseases

Human chorionic gonadotropin is a stimulator of the TSH receptor and may cause hyperthyroidism.[34] The basis for the thyrotropic effect of hCG is the structural similarity of hCG to TSH (similar α subunits and unique β subunits). In hyperthyroid patients with very high hCG levels, serum TSH may be inappropriately detectable due to the weak cross-reactivity of hCG in the radioimmunoassay for TSH. For patients with hyperthyroidism caused by trophoblastic tumors, serum hCG levels usually exceed 300 units/mL and always exceed 100 units/mL. The mean peak hCG level in normal pregnancy is 50 units/mL. On a molar basis, hCG has only 1/10,000 the activity of pituitary TSH in mouse bioassays. Nevertheless, this thyrotropic activity may be very substantial for patients with trophoblastic tumors, whose serum hCG concentrations may reach 2,000 units/mL.

THYROID AUTONOMY

Toxic Adenoma

An autonomous thyroid nodule is a discrete thyroid mass whose function is independent of pituitary and TSH control.[35] The prevalence of toxic adenoma ranges from about 2% to 9% of thyrotoxic patients, and depends on iodine availability and geographic location. Toxic adenomas arise from gain-of-function somatic mutations of the TSH receptor or, less commonly, the $G_s\alpha$ protein; more than a dozen TSH receptor mutations have been described.[12] These nodules may be referred to as *toxic adenomas,* or "hot" nodules, because of their persistent uptake on a radioiodine thyroid scan, despite suppressed uptake in the surrounding nonnodular gland (Fig. 84–5). The amount of thyroid hormone produced by an

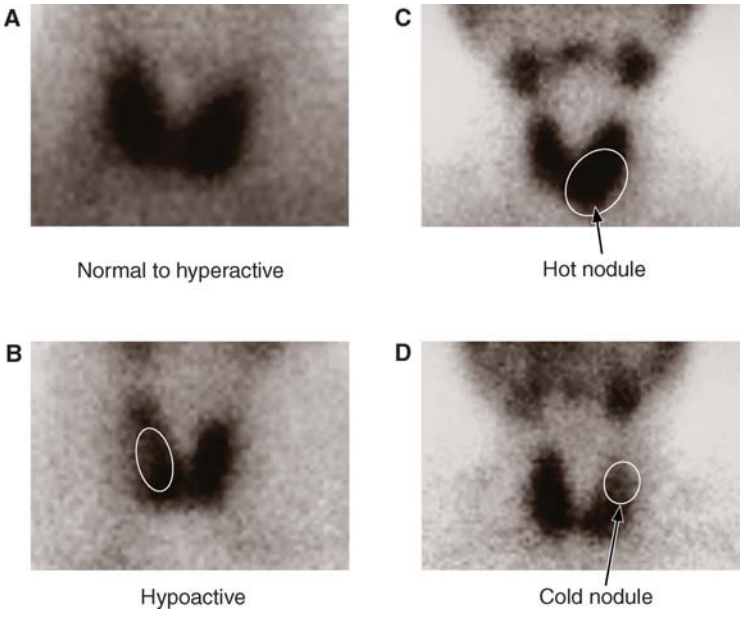

FIGURE 84-5. Radioiodine thyroid scans. A. Normal or increased thyroid uptake of iodine-125 (^{125}I). (B) Thyroid with marked decrease in ^{125}I uptake in a large palpable mass. C. Increased ^{125}I uptake isolated to a single nodule, the "hot nodule." D. Decreased thyroid ^{125}I uptake in an isolated region, the "cold nodule." *(Reproduced with permission from Molina PE. Endocrine Physiology, 2nd ed. New York: McGraw-Hill, 2006:90. Images courtesy of Dr. Luis Linares, Memorial Medical Center, New Orleans, LA.)*

autonomous nodule is mass related. Therefore, hyperthyroidism usually occurs with larger nodules (i.e., those >3 cm in diameter). Older patients (>60 years) are more likely (up to 60%) to be thyrotoxic from autonomous nodules than are younger patients (12%). There are many reports of isolated elevation of serum T_3 for patients with autonomously functioning nodules. Therefore, if the T_4 level is normal, a T_3 level must be measured to rule out T_3 toxicosis. If autonomous function is suspected but the TSH is normal, the diagnosis can be confirmed by a failure of the autonomous nodule to decrease its iodine uptake during exogenous T_3 administration sufficient to suppress TSH. Surgical resection, thionamides, percutaneous ethanol injection, and radioactive iodine (RAI) ablation are treatment options, but since thionamides do not halt the proliferative process in the nodule, definitive therapies are recommended.[36] Ethanol ablation may be associated with pain and damage to surrounding extrathyroidal tissues, limiting its acceptance in the United States. It has been hypothesized that sublethal radiation doses received by the surrounding nonnodular thyroid tissue during RAI therapy of toxic nodules may lead to induction of thyroid cancer, and excess thyroid cancer mortality has recently been associated with RAI therapy of toxic nodular disease. Thus, an autonomously functioning nodule, if not large enough to cause thyrotoxicosis, can often be observed conservatively without therapy.

Multinodular Goiters

In multinodular goiters (MNGs; Plummer disease), follicles with autonomous function coexist with normal or even nonfunctioning follicles.[35] The pathogenesis of MNG is thought to be similar to that of toxic adenoma: diffuse hyperplasia caused by goitrogenic stimuli, leading to mutations and clonal expansion of benign neoplasms.[37] The functional status of the nodule(s) depends upon the nature of the underlying mutations, whether activating such as TSH receptor mutations or inhibitory such as ras mutations. Thyrotoxicosis in a MNG occurs when a sufficient mass of autonomous follicles generates enough thyroid hormone to exceed the needs of the patient. It is not surprising that this type of hyperthyroidism develops insidiously over a period of several years and predominantly affects older individuals with long-standing goiters. The patient's complaints of weight loss, depression, anxiety, and insomnia may be attributed to old age. Any unexplained chronic illness in an elderly patient presenting with a MNG calls for the exclusion of hidden thyrotoxicosis.[38] Third-generation TSH assays and T_3 suppression testing may be useful in detecting subclinical hyperthyroidism.[39]

A thyroid scan will show patchy areas of autonomously functioning thyroid tissue intermixed with hypofunctioning areas. When the patient is euthyroid, therapy is based upon the need to reduce goiter size due to mass-related symptoms such as dysphagia. Doses of thyroid hormone sufficient to suppress TSH levels may slow goiter growth or cause some degree of shrinkage, but in general, suppression therapy for nodular disease is inadequate to address mass effect.[40] The preferred treatment for toxic MNG is RAI or surgery. Surgery is usually selected for younger patients and patients in whom large goiters impinge on vital organs. Alternatively, percutaneous injection of 95% ethanol has also been used to destroy single or multinodular adenomas with a 5-year success rate approaching 80%.

CAUSES OF THYROTOXICOSIS ASSOCIATED WITH SUPPRESSED RAIU

Inflammatory Thyroid Disease

Subacute Thyroiditis Painful subacute (granulomatous or deQuervain) thyroiditis often develops after a viral syndrome, but rarely has a specific virus been identified in thyroid parenchyma.[41] A genetic predisposition exists, with markedly higher risk for developing subacute thyroiditis for patients with HLA-Bw35. Systemic symptoms often accompany the syndrome, including fever, malaise, and myalgia, in addition to those symptoms due to thyrotoxicosis. Typically, patients complain of severe pain in the thyroid region, which often extends to the ear on the affected side.[42] With time, the pain may migrate from one side of the gland to the other. On physical examination, the thyroid gland is firm and exquisitely tender. Signs of thyrotoxicosis are present.

Thyroid function tests typically run a triphasic course. Initially, serum thyroxine levels are elevated due to release of preformed thyroid hormone from disrupted follicles. The 24-hour RAIU during this time is less than 2% due to thyroid inflammation and TSH suppression by the elevated thyroxine level. As the disease progresses, intrathyroidal hormone stores are depleted, and the patient may become mildly hypothyroid with an appropriately elevated TSH level. During the recovery phase, thyroid hormone stores are replenished, and serum TSH concentration gradually returns to normal. Recovery is generally complete within 2 to 6 months. Most patients remain euthyroid, and recurrences of painful thyroiditis are extremely rare. The patient with painful thyroiditis should be reassured that the disease is self-limited and is unlikely to recur. Thyrotoxic symptoms may be relieved with β-blockers. Aspirin (650 mg orally every 6 hours) will usually relieve the pain. Occasionally, prednisone (20 mg orally three times a day) must be used to suppress the inflammatory process. Antithyroid drugs are not indicated because they do not decrease the release of preformed thyroid hormone.

Painless Thyroiditis Since its description in 1975, painless (silent, lymphocytic) thyroiditis has been recognized as a common cause of thyrotoxicosis and may represent up to 15% of cases of thyrotoxicosis in North America.[43] In the setting of development of lymphocytic thyroiditis during the first 12 months after the end of pregnancy, the condition is also called *postpartum thyroiditis*.[44] The etiology is not fully understood and may be heterogeneous, but evidence indicates that autoimmunity underlies most cases. There is an increased frequency of HLA-DR3 and DR5 in patients with painless thyroiditis; nonendocrine autoimmune diseases are also more common. Histologically, diffuse lymphocytic infiltration is generally identified. The triphasic course of this illness mimics that of subacute thyroiditis. Most patients present with mild thyrotoxic symptoms. Lid retraction and lid lag are present, but exophthalmos is absent. The thyroid gland may be diffusely enlarged, but thyroid tenderness is absent.

The 24-hour RAIU will typically be suppressed to less than 2% during the thyrotoxic phase of painless thyroiditis. Antithyroglobulin and antithyroid peroxidase antibody levels are elevated in more than 50% of patients. Patients with mild hyperthyroidism and painless thyroiditis should be reassured that they have a self-limited disease, although patients with postpartum thyroiditis may experience recurrence of the disease with subsequent pregnancies. As with other thyrotoxic syndromes, adrenergic symptoms may be ameliorated with propranolol or metoprolol. Antithyroid drugs, which inhibit new hormone synthesis, are not indicated because they do not decrease the release of preformed thyroid hormone.

Ectopic Thyroid Tissue

Struma Ovarii Struma ovarii is a teratoma of the ovary that contains differentiated thyroid follicular cells and is capable of making thyroid hormone.[45] This extremely rare cause of thyrotoxicosis is suggested by the absence of thyroid enlargement in a thyrotoxic patient with a suppressed RAIU in the neck and no findings to suggest thyroiditis. The diagnosis is established by localizing

functioning thyroid tissue in the ovary with whole-body radioactive iodine (^{131}I) scanning. Interestingly, struma ovarii without associated hyperthyroidism is much more common than struma ovarii associated with hyperthyroidism. Because the tissue is neoplastic and potentially malignant, combined surgical and radioiodine treatment of malignant struma ovarii for both monitoring and therapy of relapse is the recommended treatment.

Thyroid Cancer In widely metastatic differentiated papillary or follicular carcinomas with relatively well-preserved function, sufficient thyroid hormone can be synthesized and secreted to produce thyrotoxicosis.[46,47] In most instances, a previous diagnosis of thyroid malignancy has been made. The diagnosis can be confirmed by whole-body ^{131}I scanning. Treatment with ^{131}I is generally effective at ablating functioning thyroid metastases.

Exogenous Sources of Thyroid Hormone

Thyrotoxicosis factitia is produced by the ingestion of exogenous thyroid hormone.[48] Obesity is the most common nonthyroidal disorder for which thyroid hormone is inappropriately used, but thyroid hormone has been used for almost every conceivable problem from menstrual irregularities and infertility to hypercholesterolemia and baldness. There is little evidence to suggest that treatment with thyroid hormone is beneficial for such conditions in euthyroid individuals. Obviously, thyrotoxicosis factitia can also occur when too large a dose of thyroid hormone is employed for conditions in which it is likely to be beneficial, such as differentiated thyroid carcinoma. Rarely, thyrotoxicosis factitia is caused by the purposeful and secretive ingestion of thyroid hormone by disturbed patients (usually with a medical background) who wish to obtain attention or lose weight.

Thyrotoxicosis factitia should be suspected in a thyrotoxic patient without evidence of increased hormone production, thyroidal inflammation, or ectopic thyroid tissue. The RAIU uptake is at low levels because the patient's thyroid gland function is suppressed by the exogenous thyroid hormone.[49] Measurement of plasma thyroglobulin (TG) is a valuable laboratory aid in the diagnosis of thyrotoxicosis factitia. TG is normally secreted in small amounts by the thyroid gland; however, when thyroid hormone is taken orally, TG levels tend to be lower than the normal range. In other entities characterized by a low RAIU, such as thyroiditis, leakage of preformed thyroid hormone results in elevated TG levels. If a history of thyroid hormone ingestion is elicited or deduced, exogenous thyroid hormone should be withheld for between 4 and 6 weeks, and thyroid function tests repeated to document that the euthyroid state has been restored. Rarely, thyroid hormone analogues or metabolites may be the drug of abuse, specific detection of which may be difficult with standard thyroid hormone assays. For example, tiratricol [triiodothyroacetic acid (TRIAC)], an endogenous metabolite of T_3 that has been used for weight loss and paradoxically by body builders, will suppress TSH at high enough doses and may cross-react in many T_3 immunoassays; thus, thyrotoxicosis factitia due to tiratricol abuse may be misinterpreted as T_3 toxicosis.[50]

Amiodarone may induce thyrotoxicosis (2% to 3% of patients), overt hypothyroidism (5% of patients), subclinical hypothyroidism (25% of patients), or euthyroid hyperthyroxinema, depending upon the underlying thyroid pathology or lack thereof.[51] Because amiodarone contains 37% iodine by weight, approximately 6 mg/day of iodine is released for each 200 mg of amiodarone, 1,000 times greater than the recommended daily amount of iodine of 200 mcg/day. As a result of this iodine overload, iodine-exacerbated thyroid dysfunction commonly occurs among those patients with preexisting thyroid disease: thyrotoxicosis in patients with hyperthyroidism or euthyroid nodular autonomy and hypothyroidism in patients with autoimmune thyroid disease. In contrast to hyperthyroidism with increased synthesis of thyroid hormone induced by amiodarone (type I), destructive thyroiditis with loss of TG and thyroid hormones also occurs (type II), typically among individuals with otherwise normal glands. The two types of amiodarone-induced thyrotoxicosis may be differentiated using color flow Doppler ultrasonography. Such distinction is critically important, given the therapeutic implications of the two syndromes: type I amiodarone-induced hyperthyroidism responds somewhat to thionamides, whereas type II may respond to glucocorticoids or iopanoic acid.[52–54] Unfortunately, however, the latter agent is no longer available. Obviously, RAI therapy is inappropriate in type I due to the drug-induced iodine excess, and in type II due to lack of increased hormone synthesis. The manifestations of amiodarone-induced thyrotoxicosis may be atypical symptoms such as ventricular tachycardia and exacerbation of underlying chronic obstructive pulmonary disease, both of which are even more significant given the severe underlying cardiac pathology that led to the use of the drug in the first place. Amiodarone also directly interferes with type I 5′-deiodinase, leading to reduced conversion of T_4 to T_3 and hyperthyroxinemia without thyrotoxicosis.

TREATMENT

Hyperthyroidism

DESIRED OUTCOMES

3 Three common treatment modalities are used in the management of hyperthyroidism: surgery, antithyroid medications, and radioactive iodine (RAI) (Table 84–5). The overall therapeutic objectives are to eliminate the excess thyroid hormone and minimize the symptoms and long-term consequences of hyperthyroidism. Therapy must be individualized based on the type and severity of hyperthyroidism, patient age and gender, existence of nonthyroidal conditions, and response to previous therapy.[55,56] Clinical guidelines for the treatment of hyperthyroidism have been published by various groups.[57–59]

NONPHARMACOLOGIC THERAPY

Surgical removal of the hypersecreting thyroid gland became feasible in 1923 when Plummer discovered that iodine reduced the gland's vascularity, making this definitive procedure possible. Surgery should be considered for patients with a large thyroid gland (>80 g), severe ophthalmopathy, and a lack of remission on antithyroid drug treatment. In case of cosmetic or pressure symptoms, the choice in MNG stands between surgery, which is still the first choice, and radioiodine if uptake is adequate (hot). In addition to surgery, the solitary nodule, whether hot or cold, can be treated with percutaneous ethanol injection therapy. If hot, radioiodine is the therapy of choice.[60] Traditional preparation of the patient for thyroidectomy includes propylthiouracil (PTU) or methimazole (MMI) until the patient is biochemically euthyroid (usually 6 to 8 weeks), followed by the addition of iodides (500 mg/day) for 10 to 14 days before surgery to decrease the vascularity of the gland. Iodine supplementation in iodine-deficient areas of the country may lead to a greater reduction in remnant volume in nontoxic goiter.[61] Propranolol for several weeks preoperatively and 7 to 10 days after surgery has also been used to maintain a pulse rate of less than 90 beats/min. Combined pretreatment with propranolol and 10 to 14 days of potassium iodide also has been advocated.

TABLE 84-5 Treatments for Hyperthyroidism Caused by Graves's Disease

Treatment	Advantages	Disadvantages	Comment
Antithyroid drugs	Noninvasive Lower initial cost Low risk of permanent hypothyroidism Possible remissions due to immune effects	Low cure rate (30%–80%; average 40%–50%) Adverse drug reactions Drug compliance	First-line treatment in children, adolescents, and in pregnancy Initial treatment in severe cases or preoperative preparation
Radioactive iodine (^{131}I)	Cure of hyperthyroidism Most cost effective	Permanent hypothyroidism almost inevitable Might worsen ophthalmopathy Pregnancy must be deferred for 6–12 months; no breast-feeding Small potential risk of exacerbation of hyperthyroidism	Best treatment for toxic nodules and toxic multinodular goiter
Surgery	Rapid, effective treatment, especially in patients with large goiters	Most invasive Potential complications (recurrent laryngeal nerve damage, hypoparathyroidism) Most costly Permanent hypothyroidism Pain, scar	Potential in pregnancy if major side-effect from antithyroid drugs Useful when coexisting suspicious nodule present Option for patients who refuse radioiodine

The overall morbidity rate with surgery is 2.7%. Hyperthyroidism persists or recurs in 0.6% to 17.9% of patients after thyroidectomy for Graves's disease and is more common in children. The most common complications of surgery include hypothyroidism (up to about 49%), hypoparathyroidism (up to 3.9%), and vocal cord abnormalities (up to 5.4%). The frequent occurrence of hypothyroidism following surgery requires periodic follow-up for identification and treatment of these patients.[62,63]

PHARMACOLOGIC THERAPY

Antithyroid Medications

Thiourea Drugs 4 Two drugs within this category, PTU and MMI, are approved for the treatment of hyperthyroidism in the United States.[64] They are classified as thioureylenes (thionamides), which incorporate an N—C—S ═N group into their ring structures.

Mechanism of action. PTU and MMI share several mechanisms to inhibit the biosynthesis of thyroid hormone.[20] These drugs serve as preferential substrates for the iodinating intermediate of thyroid peroxidase and divert iodine away from potential iodination sites in TG. This prevents subsequent incorporation of iodine into iodotyrosines and ultimately iodothyronine ("organification"). Second, they inhibit coupling of monoiodotyrosine and diiodotyrosine to form T_4 and T_3. The coupling reaction may be more sensitive to these drugs than the iodination reaction. Experimentally, these drugs exhibit immunosuppressive effects, although the clinical relevance of this finding is unclear. For patients with Graves's disease, antithyroid drug treatment has been associated with lower TSAb titers and restoration of normal suppressor T-cell function. However, perchlorate, which has a different mechanism of action, also decreases TSAbs, suggesting that normalization of the thyroid hormone level may itself improve the abnormal immune function. PTU inhibits the peripheral conversion of T_4 to T_3. This effect is acutely dose-related and occurs within hours of PTU administration. MMI does not have this effect. Over time, depletion of stored hormone and lack of continuing synthesis of thyroid hormone results in the clinical effects of these drugs.

Pharmacokinetics. Both antithyroid drugs are well absorbed (80% to 95%) from the gastrointestinal tract, with peak serum concentrations about 1 hour after ingestion. The plasma half-life ranges of PTU and MMI are 1 to 2.5 hours and 6 to 9 hours, respectively, and are not appreciably affected by thyroid status. Urinary excretion is about 35% for PTU and less than 10% for MMI. These drugs are actively concentrated in the thyroid gland, which may account for the disparity between their relatively short plasma half-lives and the effectiveness of once daily dosing regimens even with PTU. Approximately 60% to 80% of PTU is bound to plasma albumin, whereas MMI is not protein bound. Methimazole readily crosses the placenta and appears in breast milk. Older studies suggested that PTU crosses the placental membranes only one tenth as well as MMI; however, these studies were done in the course of therapeutic abortion early in pregnancy. Newer studies show little difference between fetal concentrations of PTU and MMI, and both are associated with elevated TSH in about 20% and low T_4 in about 7% of the fetuses.[65]

5 ***Dosing and monitoring.*** PTU is available as 50 mg tablets, and MMI as 5 and 10 mg tablets. MMI is approximately 10 times more potent than PTU. Initial therapy with PTU ranges from 300 to 600 mg daily, usually in three or four divided doses. MMI is given in two or three divided doses totaling 30 to 60 mg/day. Although the traditional recommendation is for divided doses, evidence exists that both drugs can be given as single daily doses. Patients with severe hyperthyroidism may require larger initial doses, and some may respond better at these larger doses if the dose is divided. The maximal blocking doses of PTU and MMI are 1,200 and 120 mg daily, respectively. Once the intrathyroidal pool of thyroid hormone is reduced and new hormone synthesis is sufficiently blocked, clinical improvement should ensue. Usually within 4 to 8 weeks of initiating therapy, symptoms will diminish and circulating thyroid hormone levels will return to normal. At this time the tapering regimen can be started. Changes in dose for each drug should be made on a monthly basis, because the endogenously produced T_4 will reach a new steady-state concentration in this interval. Typical ranges of daily maintenance doses for PTU and MMI are 50 to 300 mg and 5 to 30 mg, respectively.

If the objective of therapy is to induce a long-term remission, the patient should remain on continuous antithyroid drug therapy for 12 to 24 months. Antithyroid drug therapy induces permanent remission rates of 10% to 98%, with an overall average of about 40% to 50%.[66] This is much higher than the remission rate seen with propranolol alone, which is reported to range from 22% to 36%. Patient characteristics for a favorable outcome include older patients (>40 years), low ratio of T_4 to T_3 (<20), a small goiter (<50 g), short duration of disease (<6 months), no previous history of relapse with antithyroid drugs, duration of therapy 1 to 2 years or longer, and low TSAb titers at baseline or a reduction with treatment.[20] It is important that patients be followed every 6 to 12 months after remission occurs.

6 If a relapse occurs, alternate therapy with RAI is preferred to a second course of antithyroid drugs. Relapses seem to plateau after about 5 years and eventually 5% to 20% of patients will develop spontaneous hypothyroidism.

There has been interest in whether concurrent administration of T4 with thionamide therapy for thyrotoxicosis and subclinical hyperthyroidism can reduce autoantibodies directed toward the thyroid gland and improve remission rate. In a Japanese study, adjunctive treatment with thyroxine was associated with a 20-fold reduction in the recurrence rate of Graves's disease compared with the recurrence rate seen for patients treated with antithyroid drugs alone.[67] Attempts to reproduce these results in American and European patients with Graves's disease have failed to show any delay or reduction in the recurrence of Graves's disease with thyroxine administration.[68]

Adverse effects. Minor adverse reactions to PTU and MMI have an overall incidence of 5% to 25% depending on the dose and the drug, whereas major adverse effects occur in 1.5% to 4.6% of patients receiving these drugs.[64,69] Pruritic maculopapular rashes (sometimes associated with vasculitis based on skin biopsy), arthralgias, and fevers occur in up to 5% of patients and may occur at greater frequency with higher doses and in children. Rashes often disappear spontaneously but, if persistent, may be managed with antihistamines.

Perhaps one of the most common side effects is a benign transient leukopenia characterized by a white blood cell (WBC) count of less than 4,000/mm^3. This condition occurs in up to 12% of adults and 25% of children, and sometimes can be confused with mild leukopenia seen in Graves's disease. This mild leukopenia is not a harbinger of the more serious adverse effect of agranulocytosis, so therapy can usually be continued. If a minor adverse reaction occurs with one antithyroid drug, the alternate thiourea may be tried, but cross-sensitivity occurs for about 50% of patients.[64]

Agranulocytosis is one of the serious adverse effects of thiourea drug therapy and is characterized by fever, malaise, gingivitis, oropharyngeal infection, and a granulocyte count less than 250/mm^3.[64] These drugs are concentrated in granulocytes, and this reaction may represent a direct toxic effect rather than hypersensitivity. This toxic reaction has occurred with both thioureas, and the incidence varies from 0.5% to 6%. It is higher for patients over age 40 receiving a MMI dose greater than 40 mg/day or the equivalent dose of PTU, and is linked to HLA class II genes containing the DRB1*08032 allele.[70] Agranulocytosis usually develops in the first 3 months of therapy. Because the onset is sudden, routine monitoring is not recommended. Colony-stimulating factors have been used with some success to restore cell counts to normal, but it is unclear how effective this form of therapy is compared to routine supportive care.[71,72] Peripheral lymphocytes obtained from patients with PTU-induced agranulocytosis undergo transformation in the presence of other thioamides, suggesting that these severe reactions are immunologically mediated and patients should not receive other thionamides. Aplastic anemia has been reported with MMI and may be associated with an inhibitor to colony-forming units. Once antithyroid drugs are discontinued, clinical improvement is seen over several days to weeks. Patients should be counseled to discontinue therapy and contact their physician when flu-like symptoms such as fever, malaise, or sore throat develop.

Arthralgias and a lupus-like syndrome (sometimes in the absence of antinuclear antibodies) have been reported in 4% to 5% of patients. This generally occurs after 6 months of therapy. Uncommonly, polymyositis, presenting as proximal muscle weakness and elevated creatine phosphokinase, has been reported with PTU administration. Gastrointestinal intolerance is also reported to occur in 4% to 5% of patients. Patients receiving interferon products for hepatitis C or other disorders may develop hyper- or hypothyroidism along with liver enzyme abnormalities.[73] Hypoprothrombinemia is a rare complication of thionamide therapy. Patients who have experienced a major adverse reaction to one thiourea drug should not be converted to the alternate drug because of cross-sensitivity.

Older reports suggested that congenital skin defects (aplasia cutis) may be caused by MMI and carbimazole, although a registry review from the Netherlands could not find an association between maternal use of these drugs and skin defects.[74] However, more recently, several serious congenital malformations including tracheoesophageal fistulas and choanal atresia have been observed with MMI and carbimazole but not PTU use during pregnancy.[75–77] Thus, in the past, PTU was considered the drug of choice throughout pregnancy for women with hyperthyroidism, because of concerns about the possible teratogenic effects of MMI. However, currently heightened concerns about the greater hepatoxicity of PTU than MMI have led to the recommendation that PTU no longer be considered a first-line drug, except during the first trimester of pregnancy.

Hepatoxicity can be seen with both MMI and PTU with a prevalence of approximately 1.3%. In mice, MMI undergoes epoxidation of the C-4,5 double bond by cytochrome P450 enzymes, and after being hydrolyzed, the resulting epoxide is decomposed to form N-methylthiourea, a proximate toxicant.[78,79] At moderate doses, some authors have found that initial enzyme elevations eventually normalize in most patients with continued therapy.[78] PTU-induced subclinical liver injury is common and is usually transient and asymptomatic.[80] Thus, it has generally been thought that therapy with PTU may be continued with caution in the absence of symptoms and hyperbilirubinemia. However, a 1997 literature review documented 49 cases of hepatoxicity. Twenty-eight cases were associated with PTU use, and 21 cases were associated with MMI use. The hepatoxicity was associated with seven deaths and three deaths in the PTU and MMI groups, respectively.[81] There did not appear to be a relationship between the dose or duration of thionamide treatment and outcome. During the past 20 years of PTU use in the United States, 22 adults developed severe hepatoxcitiy leading to nine deaths and five liver transplants. The risk of this complication was greater in children (1:2,000) than in adults (1:10,000). In light of such evidence, it was recommended by the American Thyroid Association and the United States and the Food and Drug Administration that PTU not be considered as first-line therapy in either adults or children.[81,82] One of three exceptions includes the first trimester of pregnancy, when the risk of MMI-induced embryopathy may exceed that of PTU-induced hepatotoxicity.

Iodides Iodide was the first form of drug therapy for Graves's disease. Its mechanism of action is to acutely block thyroid hormone release, inhibit thyroid hormone biosynthesis by interfering with intrathyroidal iodide utilization (the Wolff-Chaikoff effect), and decrease the size and vascularity of the gland. This early inhibitory effect provides symptom improvement within 2 to 7 days of initiating therapy, and serum T_4 and T_3 concentrations may be reduced for a few weeks. Despite the reduced release of T_4 and T_3, thyroid hormone synthesis continues at an accelerated rate, resulting in a gland rich in stored hormones. The normal and hyperfunctioning thyroid soon escapes from this inhibitory effect within 1 to 2 weeks by decreasing the active transfer of iodide into the gland. Iodides are often used as adjunctive therapy to prepare a patient with Graves's disease for surgery, to acutely inhibit thyroid hormone release and quickly attain the euthyroid state in severely thyrotoxic patients with cardiac decompensation, or to inhibit thyroid hormone release following radioactive iodine therapy. However, large doses of iodine

may exacerbate hyperthyroidism or indeed precipitate hyperthyroidism in some previously euthyroid individuals (Jod-Basedow disease).[83] This Jod-Basedow phenomenon is most common in iodine-deficient areas, particularly for patients with preexisting nontoxic goiter. Iodide is contraindicated in toxic MNG.

Potassium iodide is available either as a saturated solution (SSKI), which contains 38 mg of iodide per drop, or as Lugol solution, which contains 6.3 mg of iodide per drop. The typical starting dose of SSKI is 3 to 10 drops daily (120 to 400 mg) in water or juice. There is no documented advantage to using doses in excess of 6 to 8 mg/day. When used to prepare a patient for surgery, it should be administered 7 to 14 days preoperatively. As an adjunct to RAI, SSKI should not be used before, but rather 3 to 7 days after RAI treatment, so that the radioactive iodide can concentrate in the thyroid. The most frequent toxic effect with iodide therapy is hypersensitivity reactions (skin rashes, drug fever, rhinitis, and conjunctivitis); salivary gland swelling; "iodism" (metallic taste, burning mouth and throat, sore teeth and gums, symptoms of a head cold, and sometimes stomach upset and diarrhea); and gynecomastia.

Other compounds containing organic iodide have also been used therapeutically for hyperthyroidism. These include various radiologic contrast media that share a triiodo- and monoaminobenzene ring with a propionic acid chain (e.g., iopanoic acid and sodium ipodate). The effect of these compounds is a result of the iodine content inhibiting thyroid hormone release as well as competitive inhibition of 5′-monodeiodinase conversion related to their structures, which resemble thyroid analogs.[84] Unfortunately, these extremely useful agents are no longer available in the United States

Adrenergic Blockers 7 Because many of the manifestations of hyperthyroidism are mediated by β-adrenergic receptors, β-blockers (especially propranolol) have been used widely to ameliorate thyrotoxic symptoms such as palpitations, anxiety, tremor, and heat intolerance. Although β-blockers are quite effective for symptom control, they have no effect on the urinary excretion of calcium, phosphorus, hydroxyproline, creatinine, or various amino acids, suggesting a lack of effect on peripheral thyrotoxicosis and protein metabolism. Furthermore, β-blockers do not reduce TSAb nor prevent thyroid storm. Propranolol and nadolol partially block the conversion of T_4 to T_3, but this contribution to the overall therapeutic effect is small in magnitude. Inhibition of conversion of T_4 to T_3 is mediated by *d*-propranolol, which is devoid of β-blocking activity, and *l*-propranolol, which is responsible for the antiadrenergic effects, has little effect on the conversion.

β-Blockers are usually used as adjunctive therapy with antithyroid drugs, RAI, or iodides when treating Graves's disease or toxic nodules; in preparation for surgery; or in thyroid storm. The only conditions for which β-blockers are primary therapy for thyrotoxicosis are those associated with thyroiditis. The dose of propranolol required to relieve adrenergic symptoms is variable, but an initial dose of 20 to 40 mg four times daily is effective (heart rate <90 beats/min) for most patients. Younger or more severely toxic patients may require as much as 240 to 480 mg/day because there seems to be an increased clearance rate for these patients. β-Blockers are contraindicated for patients with decompensated heart failure unless it is caused solely by tachycardia (high output). Nonselective agents and those lacking intrinsic sympathomimetic activity should be used with caution for patients with asthma and bronchospastic chronic obstructive lung disease. β-Blockers that are cardioselective and have intrinsic sympathomimetic activity may have a slight margin of safety in these situations. Other patients in whom contraindications exist are those with sinus bradycardia, those receiving monoamine oxidase inhibitors or tricyclic antidepressants, and those with spontaneous hypoglycemia. β-Blockers may also prolong gestation and labor during pregnancy. Other side effects include nausea, vomiting, anxiety, insomnia, light-headedness, bradycardia, and hematologic disturbances.

Antiadrenergic agents such as centrally acting sympatholytics and calcium channel antagonists may have some role in the symptomatic treatment of hyperthyroidism. These drugs might be useful when contraindications to β-blockade exist. When compared with nadolol 40 mg twice daily, clonidine 150 mcg twice daily reduced plasma catecholamines, whereas nadolol increased both epinephrine and norepinephrine after 1 week of treatment. Diltiazem 120 mg given every 8 hours reduced heart rate by 17%; fewer ventricular extrasystoles were noted after 10 days of therapy, and diltiazem has been shown to be comparable to propranolol in lowering heart rate and blood pressure.

Radioactive Iodine Although other radioisotopes have been used to ablate thyroid tissue, sodium iodide-131 (^{131}I) is considered to be the agent of choice for Graves's disease, toxic autonomous nodules, and toxic MNGs.[85,86] RAI is administered as a colorless and tasteless liquid that is well absorbed and concentrates in the thyroid. Sodium iodide-131 is a β-and γ-emitter with a tissue penetration of 2 mm and a half-life of 8 days. Other organs take up ^{131}I, but the thyroid gland is the only organ in which organification of the absorbed iodine takes place. Initially, RAI disrupts hormone synthesis by incorporating into thyroid hormones and TG. Over a period of weeks, follicles that have taken up RAI, and surrounding follicles develop evidence of cellular necrosis, breakdown of follicles, development of bizarre cell forms, nuclear pyknosis, and destruction of small vessels within the gland, leading to edema and fibrosis of the interstitial tissue. Predictors of successful treatment with RAI include higher ablative dose, female gender, lower free thyroxine levels at diagnosis, and absence of a palpable goiter.[87] Pregnancy is an absolute contraindication to the use of RAI since radiation will be delivered to the fetal tissue, including the fetal thyroid.

β-Blockers may be given any time without compromising RAI therapy, accounting for their role as a mainstay of adjunctive therapy to RAI treatment. If iodides are administered, they should be given 3 to 7 days after RAI to prevent interference with the uptake of RAI in the thyroid gland. Because thyroid hormone levels will transiently increase following RAI treatment due to release of preformed thyroid hormone, patients with cardiac disease and elderly patients are often treated with thionamides prior to RAI ablation. Occasionally, for patients with underlying cardiac disease, it may be necessary to reinstitute antithyroid drug therapy following radioactive iodine ablation. The standard practice is to withdraw the thionamide 4 to 6 days prior to RAI treatment and to reinstitute it 4 days after therapy is concluded. Administering antithyroid drug therapy following RAI treatment may result in a higher rate of posttreatment recurrence or persistent hyperthyroidism.[86] Pretreatment with PTU may lead to higher rates of treatment failure, but this does not appear to be the case with MMI pretreatment.[88,89] Use of lithium, as adjunctive therapy to RAI therapy, has multiple benefits of increasing the cure rate, shortening the time to cure, and preventing posttherapy increase in thyroid hormone levels.[90] Lithium is likely to achieve these effects by increasing RAI retention in the thyroid and inhibiting thyroid hormone release from the gland.

Corticosteroid administration will blunt and delay the rise in antibodies to the TSH receptor, TG, and thyroid peroxidase while reducing T_3 and T_4 concentrations following RAI. Bartalena and associates found no progression in ophthalmopathy for patients receiving prednisone after RAI compared with MMI (2% to 3% worsened) or no other treatment (5% with persistent worsening).[49] Theoretically, if shared thyroidal and orbital antigen is involved in the pathogenesis of Graves's ophthalmopathy, antigen released with RAI treatment could aggravate preexisting eye disease. Note also that thyroid ablation may decrease eye disease in the long

term by removing the source of antigen, but it is unclear if RAI differs from surgery or thionamide for the risk of worsening eye disease.[91]

Destruction of the gland attenuates the hyperthyroid state, and hypothyroidism commonly occurs months to years following RAI.[92] The goal of therapy is to destroy overactive thyroid cells, and a single dose of 4,000 to 8,000 rad results in a euthyroid state in 60% of patients at 6 months or less. The remaining 40% become euthyroid within 1 year, requiring two or more doses. It is advisable that a second dose of RAI be given 6 months after the first RAI treatment if the patient remains hyperthyroid. Variables that predict an unsuccessful outcome of RAI include gender (men are less likely to develop hypothyroidism), race, the size of the thyroid (euthyroidism is less likely in large glands), severity of disease, and perhaps a higher level of TSAb. In a recent study predictors of successful treatment with RAI included higher ablative dose, female gender, lower free thyroxine levels at diagnosis, and absence of a palpable goiter.[93] The acute, short-term side effects of ^{131}I therapy are minimal and include mild thyroidal tenderness and dysphagia. Concern over increased risk of mutations and congenital defects now appears to be unfounded because long-term follow-up studies have not revealed increased risk for these complications.[94] In studies examining the risk of malignancies after RAI therapy, there seems to be a small but significant increase in the risk of cancer of the small bowel and thyroid.[94] Although RAI is very effective in the treatment of hyperthyroidism, long-term follow-up from Great Britain suggests that among patients with hyperthyroidism treated with RAI, mortality from all causes and mortality resulting from cardiovascular and cerebrovascular disease and fracture are increased.[95]

A common approach to Graves's hyperthyroidism is to administer a single dose of 5 to 15 mCi (80 to 200 μCi/g of tissue).[86] The optimal method for determining ^{131}I treatment doses for Graves's hyperthyroidism is unknown, and techniques have varied from a fixed dose to more elaborate calculations based on gland size, iodine uptake, and iodine turnover. In a trial of 88 patients with Graves's disease, no difference in outcome was seen among high or low, fixed or adjusted doses.[96] Thyroid glands estimated to weigh >80 g may require larger doses of RAI. Larger doses are likely to induce hypothyroidism and are seldom given outside the United States due to the imposition of stringent safety restrictions. For example, in the United Kingdom, a nursery school teacher is advised to stay out of school for 3 weeks following a 15 mCi dose of ^{131}I.[97]

EVALUATION OF THERAPEUTIC OUTCOMES: HYPERTHYROIDISM

After therapy (surgery, thionamides, or RAI) for hyperthyroidism has been initiated, patients should be evaluated on a monthly basis until they reach a euthyroid condition. Clinical signs of continuing thyrotoxicosis (tachycardia, weight loss, and heat intolerance, among others) or the development of hypothyroidism (bradycardia, weight gain, and lethargy, among others) should be noted. β-Blockers may be used to control symptoms of thyrotoxicosis until the definitive treatment has returned the patient to a euthyroid state. Once thyroxine replacement is initiated, the goal is to maintain both the free thyroxine level and the TSH concentration in the normal range. Once a stable dose of thyroxine is identified, the patient may be followed up every 6 to 12 months.

Finally, a common, potentially confusing clinical situation should be mentioned. Why are the TSH concentrations suppressed for some patients who are clinically hypothyroid and who have a low free T_4 level? For patients with long-standing hyperthyroidism, the pituitary thyrotrophs responsible for making TSH become atrophic. The average amount of time required for these cells to resume normal functioning is 6 to 8 weeks.[98] Therefore, if a thyrotoxic patient has his or her free T_4 concentration lowered rapidly, before the thyrotrophs resume normal function, a period of "transient central hypothyroidism" will be observed.

SPECIAL CONDITIONS

Graves's Disease And Pregnancy[99]

Inappropriate production of hCG is a cause of abnormal thyroid function tests during the first half of pregnancy, and hCG can cause either subclinical (normal T_4, suppressed TSH) or overt hyperthyroidism.[100,101] This is because the homology of hCG and TSH leads to hCG-mediated stimulation through the TSH receptor. A recent study showed that at hCG concentrations greater than 400,000 international units/L, TSH levels were invariably suppressed and free thyroxine levels were generally above the normal range. Most patients with hCG greater than 200,000 international units/L did not have symptoms of hyperthyroidism.[102] The variability of the thyrotropic potency of hCG is believed to depend on its carbohydrate composition.

Hyperthyroidism during pregnancy is almost solely caused by Graves's disease, with approximately 0.1% to 0.4% of pregnancies affected. Although the increased metabolic rate is usually well tolerated in pregnant women, two symptoms suggestive of hyperthyroidism during pregnancy are failure to gain weight despite good appetite and persistent tachycardia. There is no increase in maternal mortality or morbidity in well-controlled patients; however, postpartum thyroid storm has been reported in about 20% of untreated individuals. Fetal loss is also more common, due to the facts that spontaneous abortion and premature delivery are more common in untreated pregnant women, as are low-birth-weight infants and eclampsia. Transplacental passage of TSAb may occur, causing fetal as well as neonatal hyperthyroidism.[103] An uncommon cause of hyperthyroidism is molar pregnancy; women present with a large-for-dates uterus and evacuation of the uterus is the preferred management approach.[104]

Because RAI is contraindicated in pregnancy and surgery is usually not recommended (especially during the first trimester), antithyroid drug therapy is usually the treatment of choice. Methimazole readily crosses the placenta and appears in breast milk.

PTU is considered the drug of choice during the first trimester of pregnancy, with the lowest possible doses used to maintain the maternal T_4 level in the high-normal range.[82,87] During this period the risk of MMI-associated embryopathy is believed to outweigh that of PTU-associated hepatoxicity. To prevent fetal goiter and suppression of fetal thyroid function, PTU is usually prescribed in daily doses of 300 mg or less and tapered to 50 to 150 mg daily after 4 to 6 weeks. PTU doses of less than 200 mg daily are unlikely to produce fetal goiter.[105] During the second and third trimesters, when the critical period of organogenesis is complete, MMI is thought to be the drug of choice because of the greater risk of hepatoxicity with PTU.[82,87] Thionamide doses should be adjusted to maintain free T4 within 10% of the upper normal limit of the nonpregnant reference range.[99] During the last trimester, TSAbs fall spontaneously, and some patients will go into remission so that antithyroid drug doses may be reduced. A rebound in maternal hyperthyroidism occurs in about 10% of women and may require more intensive treatment postpartum than in the last trimester of pregnancy.[103] For example, a recent study of patients who were euthyroid after thionamide discontinuation and subsequently became pregnant showed a relative risk of a relapse of hyperthyroidism of 4.26 ocurring 4 to 8 months after delivery.[106]

Neonatal and Pediatric Hyperthyroidism

Following delivery, some babies of hyperthyroid mothers will be hyperthyroid due to placental transfer of TSAbs, which stimulates thyroid hormone production in utero and postpartum.[107,108] This is likely if the maternal TSAb titers were quite high. The disease is usually expressed 7 to 10 days postpartum and treatment with antithyroid drugs (PTU 5 to 10 mg/kg per day or MMI 0.5 to 1 mg/kg per day) may be needed for as long as 8 to 12 weeks until the antibody is cleared (immunoglobulin G half-life is about 2 weeks). Iodide (potassium iodide 1 drop per day or Lugol solution 1 to 3 drops per day) and sodium ipodate may be used for the first few days to acutely inhibit hormone release.

Childhood hyperthyroidism has classically been managed with either PTU or MMI. Long-term follow-up studies suggest that this form of therapy is quite acceptable, with 25% of a cohort experiencing remission every 2 years.[109] Again, current recommendations suggest use of MMI as a first-line agent in both adults and children.

Thyroid Storm

Thyroid storm is a life-threatening medical emergency characterized by decompensated thyrotoxicosis, high fever (often >103°F), tachycardia, tachypnea, dehydration, delirium, coma, nausea, vomiting, and diarrhea.[22] Although Graves's disease and less commonly toxic nodular goiter are usually the underlying thyrotoxic pathology, at least two cases of subacute thyroiditis leading to thyroid storm have been reported.[110–112] Precipitating factors for thyroid storm include infection, trauma, surgery, RAI treatment, and withdrawal from antithyroid drugs. Although the duration of clinical decompensation lasts for an average duration of 72 hours, symptoms may persist up to 8 days. With aggressive treatment, the mortality rate has been lowered to 20%. The following therapeutic measures should be instituted promptly: (1) suppression of thyroid hormone formation and secretion, (2) antiadrenergic therapy, (3) administration of corticosteroids, and (4) treatment of associated complications or coexisting factors that may have precipitated the storm. Specific agents used in thyroid storm are outlined in Table 84–6. PTU in large doses is generally the preferred thionamide because, in addition to interfering with the production of thyroid hormones, it also blocks the peripheral conversion of T_4 to T_3. A theoretical advantage of MMI is that it has a longer duration of action. If patients are unable to take medications orally, the tablets can be crushed into suspension and instilled by gastric or rectal tube[113] or given intravenously.[114] Iodides, which rapidly block the release of preformed thyroid hormone, should be administered after PTU is initiated to inhibit iodide utilization by the overactive gland. If iodide is administered first, it could theoretically provide substrate for even higher levels of hormone.

Antiadrenergic therapy with the short-acting agent esmolol is preferred, both because it may be used in the patient with pulmonary disease or at risk for cardiac failure and because its effects may be rapidly reversed.[115] Corticosteroids are generally recommended, although there is no convincing evidence of adrenocortical insufficiency in thyroid storm, and the benefits derived from steroids may be caused by their antipyretic action and their effect of stabilizing blood pressure.[22] General supportive measures, including acetaminophen as an antipyretic (do not use aspirin or other nonsteroidal antiinflammatory agents because they may displace bound thyroid hormone), fluid and electrolyte replacement, sedatives, digitalis, antiarrhythmics, insulin, and antibiotics should be given as indicated. Plasmapheresis and peritoneal dialysis have been used to remove excess hormone (and to remove thyroid-stimulating immunoglobulins in Graves's disease) when the patient has not responded to more conservative measures, although these measures do not always work.[116]

TABLE 84-6 Drug Dosages Used in the Management of Thyroid Storm

Drug	Regimen
Propylthiouracil	900–1,200 mg/day orally in four or six divided doses
Methimazole	90–120 mg/day orally in four or six divided doses
Sodium iodide	Up to 2 g/day IV in single or divided doses
Lugol's solution	5–10 drops three times a day in water or juice
Saturated solution of potassium iodide	1–2 drops three times a day in water or juice
Propranolol	40–80 mg every 6 h
Dexamethasone	5–20 mg/day orally or IV in divided doses
Prednisone	25–100 mg/day orally in divided doses
Methylprednisolone	20–80 mg/day IV in divided doses
Hydrocortisone	100–400 mg/day IV in divided doses

HYPOTHYROIDISM

Hypothyroidism is defined as the clinical and biochemical syndrome resulting from decreased thyroid hormone production.[117] Overt hypothyroidism occurs in 1.5% to 2% of women and 0.2% of men, and its incidence increases with age. In the Third National Health and Nutrition Examination Survey, levels of serum TSH and total thyroxine (T_4) were measured in a representative sample of adolescents and adults (age 12 or older). Among 16,533 people who neither were taking thyroid medication nor reported histories of thyroid disease, 3.9% had subclinical hypothyroidism (serum TSH >4.5 milli-international units/L; and T_4 normal), and 0.2% had "clinically significant" hypothyroidism (TSH >4.5 milli-international units/L; and T_4 <4.5 mcg/dL).[21] The vast majority of patients have primary hypothyroidism due to thyroid gland failure due to chronic autoimmune thyroiditis. Special populations with higher risk of developing hypothyroidism include postpartum women, individuals with a family history of autoimmune thyroid disorders and patients with previous head and neck or thyroid irradiation or surgery, other autoimmune endocrine conditions (e.g., type 1 diabetes mellitus, adrenal insufficiency, and ovarian failure), some other nonendocrine autoimmune disorders (e.g., celiac disease, vitiligo, pernicious anemia, Sjögren' syndrome, and multiple sclerosis), primary pulmonary hypertension, and Down and Turner syndromes. Secondary hypothyroidism due to pituitary failure is uncommon but should be suspected in a patient with decreased levels of thyroxine and inappropriately normal or low TSH levels. Most patients with secondary hypothyroidism due to inadequate TSH production will have clinical signs of more generalized pituitary insufficiency, such as abnormal menses and decreased libido, or evidence of a pituitary adenoma, such as visual-field defects, galactorrhea, or acromegaloid features, but isolated TSH deficiency can be congenital or acquired as a result of autoimmune hypophysitis.[118] Generalized (peripheral and central) resistance to thyroid hormone is extremely rare.

Thyroid hormone is essential for normal growth and development during embryonic life. Uncorrected thyroid hormone deficiency during fetal and neonatal development results in mental retardation and/or cretinism. There is slowing of physical and mental activity, as well as of cardiovascular, gastrointestinal, and neuromuscular function.

A rise in the TSH level is the first evidence of primary hypothyroidism. Many patients will have a free T_4 level within the normal range (compensated hypothyroidism) and few, if any, symptoms of

CLINICAL PRESENTATION OF HYPOTHYROIDISM

General

- Hypothyroidism can lead to a variety of end-organ effects with a wide range of disease severity, from entirely asymptomatic individuals to patients in coma with multisystem failure. In the adult, manifestations of hypothyroidism are varied and nonspecific. In the child, thyroid hormone deficiency may manifest as growth or intellectual retardation.

Symptoms

- Common symptoms of hypothyroidism include dry skin, cold intolerance, weight gain, constipation, and weakness. Complaints of lethargy, depression, fatigue or loss of ambition and energy are also common but are less specific. Muscle cramps, myalgia, and stiffness are frequent complaints of hypothyroid patients. Menorrhagia and infertility may present commonly in women.

Signs

- Objective weakness is common, with proximal muscles being affected more than distal muscles. Slow relaxation of deep tendon reflexes is common. The most common signs of decreased levels of thyroid hormone include coarse skin and hair, cold or dry skin, periorbital puffiness, and bradycardia. Speech is often slow as well as hoarse. Reversible neurologic syndromes such as carpal tunnel syndrome, polyneuropathy, and cerebellar dysfunction may also occur. Galactorrhea may be found in women.

Diagnosis

- In primary hypothyroidism, TSH serum concentration should be elevated. In secondary hypothyroidism, TSH levels may be within or below the reference range; when TSH bioactivity is altered, the levels reported by immunoassay may even be elevated.
- Free and/or total T_4 and T_3 serum concentrations should be low.

Other tests

- Antithyroid peroxidase antibodies and anti-TG antibodies are likely to be elevated in autoimmune thyroiditis.

hypothyroidism. As the disease progresses, the free T_4 concentration will drop below the normal level. Interestingly, because of TSH stimulation, thyroidal production will shift toward greater amounts of T_3, and thus T_3 concentrations will often be maintained in the normal range in spite of a low T_4. The RAIU is not a useful test in the evaluation of a hypothyroid patient, as it may be low, normal, or even elevated.

CAUSES OF HYPOTHYROIDISM

Table 84–7 outlines the causes of hypothyroidism.

Chronic Autoimmune Thyroiditis
